SEA TELEGRAPHY IN SPECIAL RELATION TO THE LOSS OF THE VANGUARD.*

By Mr. W. H. BAILEY.

To communicate by signal is a practice of considerable antiquity, but the time at our disposal will only permit of a very brief reference to some of the early means by which people, separated by distance, have been able to communicate with one another. The prophet Jeremiah exhorts the children of Benjamin to set up a sign of fire; and in profane history we have fires, beacons, and torches often alluded to. Agamemnon communicated with his Queen by means of beacon fires on the mountain tops. Again, a very ingenious telegraph is described by Æneas, who lived in the time of Aristotle. It consisted of two tubs, marked inside to indicate the depth of the water, and furnished with small taps. The tubs were filled with water and placed on distant hills in charge of men with torches. Upon the elevation of a torch twice both taps were started simultaneously, and the water, of course, ran away. But the moment a torch was elevated by the sender of the message the taps were stopped. Now, supposing that each inch of water signified a particular message, it will be seen how, by permitting the water to fall to any given level, the message indicated by that level would be conveyed. This system must have been adopted from the Clepsydra, or water clock, which indicated the time of day by the height of water in a similar way. The ancient inhabitants of America would seem to have had communications of a similar nature. The use of torches and beacon fires by night would naturally lead to the use of the semaphore by day—including under this designation flags or wooden erections with wing pieces or circular plates, such as are in general use to-day on railways. The semaphore was brought into celebrity in France by three brothers named Chappe, who by means of wing pieces attached to the ends of a bar of wood were able to make a great number of combinations. To Claude Chappe the happy idea first occurred, but he paid the penalty of being an inventor in those days, since his first instruments were destroyed by the ignorant populace. Nothing daunted, however, he continued his efforts, and when by his system the first news of a French victory was sent to Paris, he and his brothers became the pride of the French people. The system soon became well known, and additions were made to it by subsequent inventors. Lord George Murray proposed his shutter telegraph in 1795. It consisted of six shutters working on pivots, and by exhibiting one or more in combination many messages could be sent according to a pre-arranged code. Messages were sent by this means from London to Dover in ten or twelve minutes, and the plan was adopted by the Admiralty, and used many years. But in foggy weather it was useless, and relays of horses had to carry the news. A remarkable proof of its inutility under such circumstances was manifested when one of Wellington's victories over the French was being announced. The words "Wellington defeated" were signalled, when a dense fog came down, and the rest of the message could not be sent. The consternation in London was very great until the conclusion of the message arrived, and it was found to read "Wellington defeated the French." In the meantime, however, the navy had made but little advance, and ships could only speak each other by a clumsy system of flags by day and coloured lanterns by night. Rear Admiral Sir Home Popham, in 1801, introduced several modifications in semaphores for land and sea, and also a system of spelling by means of flags. His ideas were adopted, and the celebrated words of Lord Nelson, "England expects that every man this day will do his duty," were the first transmitted to the fleet by the new system, which was then on its trial as an experiment. Probably the greatest advance made in signalling at sea, however, has been the results of the joint labours of Captain Colomb and Major Bolton. These gentlemen have introduced a system of telegraphing at night by means of flash lights, using oil lanterns for short, and magnesium and other lights for great distances. The inventions of these gentlemen have been so good that they have been adopted by the British and Foreign Governments for communicating between vessels at night. They were used also on land in the Abyssinian expedition. Captain Colomb and Major Bolton in their flash light system have incorporated the idea of short and long lights, but it will be obvious that the invention, excellent as it is, will not meet all the conditions under which signalling is necessary, for the very best system of telegraphing at sea by signs may be rendered absolutely useless by a dense fog or smoke. I hope at some future time to explain the details of the system to this society, since the inventors have kindly placed their models and apparatus at my disposal. Just now, however, it will be well to bear in mind that the system may be worked in combination with that which I have specially to explain to you in such a manner that signals may be both seen and heard.

Hence it will be seen that telegraphs may broadly be divided into those which speak by sound, and those which speak by sight. In the first we may include guns, trumpets, drums, gongs, and steam whistles, and in the latter flags, torches, lanterns, fires, semaphores, needles, and other instruments of a like character. We are chiefly concerned, however, with telegraphing by sound, of which I will now proceed to speak.

My attention was first drawn to this subject by Captain Brent, then commander of H.M.S. Bellerophon, and having made many experiments I have come to the conclusion that it is possible for vessels to speak each other in dense fogs, and under other conditions at distances apart ranging from three miles up to at least six or eight, according to the conditions of the atmosphere. The experiments made by Dr. Tyndall in May, 1873, demonstrated the possibility of hearing a sound of a definite volume at distances varying from three and a-half to twelve and three-quarter miles, according to the atmospheric conditions; but that on one occasion when the wind was against the sound it could be heard at a distance of nine and a-quarter miles: and it is my object in the course of this paper, and with the aid of the experiments which are to follow, to show that the sound can be so utilised and directed as to almost literally talk. I may mention that the whistle on the table has been made from the pattern that I prepared for the Trinity House experiments on sound, conducted at Dover by Professor Tyndall. I believe that it was there demonstrated that steam horns were better than whistles. I may be permitted, however, to observe that these horns cost exactly five and one-third times more money than the whistles, and I have a strong impression that if the cost of both had been equal, the verdict would have been otherwise. It seems from this that making a noise in the world is simply a financial problem after all.

To speak first of vessels at sea, it may be said that the most dangerous conditions under which a vessel can move are such as prevailed recently upon the occasion of the Vanguard disaster. As dense fogs invariably occur in calm weather it will be apparent that sound telegraphs can be used with the greatest facility when there is most serious occasion for their services. I hope I shall be able to prove to you that it is perfectly possible and comparatively easy for one man to speak to another at, say, a speed varying from ten to twenty, and even up to thirty words per minute, according to distance. The instrument which I propose to use is a large steam whistle so designed that a pianoforte touch will give a large opening to the steam way, and enable a percussive short or long sound to be emitted. The diagram on the wall shows a sectional view of my patent steam whistle telegraph. It will be observed that the centre spindle has upon it two equilibrium valves, which are so balanced as to be affected by the lever with the greatest ease, even though there may be a pressure of eighty or a hundred pounds to the square inch on the valve faces. This arrangement makes it possible for large whistles to be worked whose supply pipes may be three, four, five, or six inches in diameter. The bell of the whistle is adjustable in order that high or low-pressure steam may be used, and the best results be thus obtained from the steam that the boiler may carry when it is at work. This steam whistle I propose to elevate about ten or twelve feet above the head of the operator, who by means of a chain attached to the lever, and a handle, can work it and send messages by means of the dot and dash system, using either the Morse or any other code or alphabet. I prefer the Morse code for what appear to me sufficiently weighty reasons. In the first place, this code is already in use wherever the electric telegraph system is known. Every telegraphic instrumentalist in this country, in France, America, Russia, India, Germany, or anywhere else, uses this alphabet. And further it is fortunate that this alphabet can be either written, seen, or heard. This peculiarity is particularly serviceable in this instance, and I wish specially to draw attention to the universal adoption of the Morse code, because if this system of signalling is to be introduced, to be of real service, it must be international, in order that the vessels sailing under all flags may be able to use it with mutual benefit. This fact enables us to see that a staff already educated is immediately available. I have made experiments in various parts of this country, and have on three separate occasions obtained the services of young men from the postal telegraph stations in the towns in which I have happened to be, and they have instantly understood the dot and dash sound telegraphy, and have been able to use my small instruments without any previous practice at all. I have not been able to make experiments of a thoroughly definite nature on long distances to ascertain as to how far sound may be sent by one of these instruments, but I believe that one of 12in. diameter is quite capable of being used successfully through a fog for a distance of six miles. That is to say, that should two vessels get separated in a fog they would be able to communicate with each other, supposing them both to be provided with 12in. whistles, even should they be six miles from one another. But I have made definite experiments with whistles 6in. in diameter, and by one of that power sound may be distinctly heard and interpreted over a distance of three miles.

I exhibit a cast iron plate having the Morse alphabet in raised characters upon it. This I would place immediately below the telegraph whistle, so that any one wishing to send a message, though he should not understand the alphabet, might yet do so readily by reference to the table. And those not technically acquainted with the system might easily master it. I am told by those connected with electric telegraphs in this country that it takes a skilled lad four or five days, and a man from a week to a fortnight, according to his capacity.

The utility of such a system as this is at once apparent when the circumstances under which the late collision between the Iron Duke and the Vanguard took place are remembered. The Trinity House regulations at present are that during a fog every steam vessel must whistle under certain conditions; but the whistle is unintelligible, or at least unintelligent, and indicates very obscurely the whereabouts of the vessel blowing the whistle. In fact, if any one will shut his eyes and listen to a steam whistle, he would find it extremely difficult to tell whether it was before or behind him.

The want of this definite information was lamentably manifested in the recent collision. But if both vessels had been fitted with such instruments as I have described, they would not only have heard the whistle, but at the comparatively short distance which separated them they could have carried on a conversation, could have asked each other the direction in which each was going, the rate of the speed, or in short almost anything at all. Thus it will be at once seen how invaluable such a provision would have been.

Although I use the Morse code in order to show to-night the velocity with which telegrams may be sent, it is possible that codes already in use in the navy for flashlight purposes may be better than the Morse alphabet. Naval men will be the best judges of this if the instruments are practically tried. At the conclusion of my remarks, any of you who will write a short sentence may have it telegraphed into this room from an instrument 12in. in diameter, which is fixed on a boiler a few hundred yards from the building, and thus some idea of the time taken to send information may be gained.

There are also small instruments on the table which we will use for sending messages from one room to another.

It has been proposed by Mr. Swann that whistles should be sounded by the revolutions of a drum, like an organ barrel, and driven by a small engine. A stereotyped international code could be continually sounded in a fog, indicating the exact course of the vessel. Mr. Swann and I have endeavoured to bring his invention into use at a great cost to ourselves, but it is obvious that this system would be useless unless made compulsory by the authorities.

But although I have so far called special attention to the utility of my system in foggy weather, it must have been apparent that it would be quite as useful under more favourable conditions. By this means, indeed, news could be communicated from one vessel to another as fast as a man could write, and with much greater facility than under the condition of things now prevailing. A vessel coming from a distant quarter of the globe meeting another, and having important intelligence to communicate, may do so by simply diminishing her speed, and no time need be wasted while boats are being sent with letters. What a great boon this would be to the newspaper press in general may be readily understood, when it is borne in mind that the most that it is possible to obtain from outward-bound vessels are a few brief

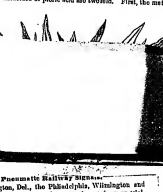
cut off and laid in the sun on moist sand, where they root freely in a few weeks, and often keep on flowering as though nothing had happened.

A Profitable Source of Picric Acid.

G. C. Wittstein calls attention to a new source of picric acid. This is a long and well known drug, the resin of *xanthorrhœa arborea*, a plant which is a native of Australia. It is known as acaroid resin and as the yellow resin of Botany Bay in New Holland (*resina acaroidis* and *resina lutea Novi Belgii*). The advantages of using this substance for the manufacture of picric acid are twofold. First, the nitric acid adhering ... driven off at 212° Fah. The total residue weighed 100 grains, almost ⅓ of the resin taken; it was yellow and crystalline, and contained nothing amorphous but single crystals of oxalic acid. The picric acid thus obtained, after recrystallizing to secure the oxalic acid, weighed 75 grains. Hence, the yield is 50 per cent of the crude material.



Fused Boracic Acid.

Fused boracic acid, which approaches glass in some of its external characteristics, presents some properties worthy of note. In the viscid state it may be drawn out into threads, which solidify rapidly, and from this point of view its ductility rather resembles that of silica than of glass. Its hardness, between 4 and 5, places it between fluor spar and apatite; it scratches glass, and is with difficulty attacked by sand, and even by emery, dry or with oil. It takes seven to eight times as much time in grinding as glass under the same circumstances. This resistance to friction, which does not accord with its hardness, depends doubtless, as M. Damour has recognized in the case of other minerals, on a speciality of structure. Molted boracic acid, in mass, becomes slowly hydrated in contact with water. In powder it is acted on rapidly, as shown by Ebelmen. If the powder is sprinkled with water, its temperature may rise to 100°. Boracic acid is chiefly remarkable for the persistence of its temper. If poured upon a cold metallic surface, glassy plates are obtained, the under surface of which, chilled by the metal, is more strongly tempered and more expanded than the upper. Hence results a flection which may be strong enough to cause the rupture of the plate and its projection in fragments. If poured into oil it may be obtained in small masses with short tails, under the same conditions as Prince Rupert's drops. A tempered plate of boracic acid, with parallel surfaces, acts upon polarized light like tempered glass; but while the latter loses this property by re-heating, boracic acid preserves it with great tenacity.—*P. de Luynes.*

Eighty Miles an Hour in Pneumatic Tubes.—The Atmospheric Post between Paris and Versailles.

S.A.
Sep. 75

The National Assembly of France holds its sittings in Versailles, a kingly residence distant some eleven miles from Paris. The latter is the real seat of government, and it was therefore of great importance to introduce a means of communication by which official documents could be transmitted between the two places, at any moment when required, with great rapidity. For this purpose the pneumatic method has been put into operation, with much success, and it is stated that letters and packages are now sent through, in either direction, in eight minutes' time, being at an average velocity of more than eighty miles an hour.

To produce this enormous velocity—the tubes being only four inches in diameter—requires the use of three steam engines having an aggregate of one hundred and fifty horse power, besides other extensive apparatus, which we will briefly describe, quoting from a recent number of the *Engineer.*

A report on the system of M. Crespin, on the application of pneumatic power over long distances, has been reported upon by M. Tresca, of the Conservatoire des Arts et Métiers, with the Academy of Sciences, and the report is now published. We copy from the *Engineer.*

When it was found necessary to connect Paris and Versailles by means of a pneumatic tube, it was impossible to make use of the method adopted in Paris, which only gives the required speed over a distance of about 1 mile. The problem was to apply the same force along a line from 11 to 12 miles in length. This result has been obtained by the adoption of an apparatus called a relay, which, placed at various points along the line, acts upon the train and urges it at full speed to the next station. The column of air within the tube is set in action by forcing or by exhaustion, and the two operations are employed concurrently, but in a novel manner.

As in the pneumatic telegraph, M. Crespin uses a series of boxes to form a train; the impulse is given by forcing the air in at one end of the tube and exhausting it at the other; the pressure accumulated in the reservoirs comes into action at the moment the train passes a relay, and continues until the arrival of the train at the next post, when it is taken up by another reservoir, and so on to the end.

The line is double, up and down, and each is divided into sixteen sections of 3,650 feet in length, and each section has its relay. The necessary motive power is obtained from three stations, one at each end of the line, the other in the middle. The last is the most important, and comprises two engines of fifty horse power each, with pumps capable of exhausting the 280 cubic yards contained in the part of the line it serves in ten minutes, at the same time storing it in the reservoirs under the pressure of one atmosphere, necessary to supply successively behind the train 188 cubic yards

Pneumatic Railway Signals.

At Wilmington, Del., the Philadelphia, Wilmington and Baltimore Railroad Company has recently put down, on trial, a new railway signal and gate system. Along or between the tracks, or under the road, a pipe is laid, 2 inches in diameter, in which compressed air, 85 lbs. to the inch pressure, is carried. When the train moves out of the depot, the locomotive strikes a lever; and at the first street which the track crosses, a gong or bell is set ringing, to warn persons that a train is approaching, and a gate extending across the street descends to within two feet of the ground. The gate remains closed until the train has passed. The locomotive then strikes another lever, when another bell is rung, and another gate a square ahead is closed; and the gate behind the train is caused to rise to its place, and that crossing is left free. In this manner every train that passes through a city is made automatically to fence itself in, as it were, by closing and opening gates over each street, one or two squares in advance as may be desired.

When the train starts, by its striking the lever already described, a danger signal is instantly thrown around at right angles to the track behind the train, and another a mile ahead of it. When this one is reached another lever is struck, and the last mentioned signals are thrown back to their former positions, showing the first mile to be clear; and the two other signals, one behind and one a mile ahead of the train, are exposed, and so from mile to mile along the whole road. At every point of its progress a train is thus between two signals, one to warn trains coming toward it, the other to warn trains following it.

to the Roman period. On the latter supposition they would seem to show that too much time had generally been ascribed for the accumulation of deposits. Mr. Deas, C.E., remarked upon it as a noticeable fact that the canoe recently discovered near the large crane at Stobcross had been embedded at a point on a level with the Roman roadway. He intended shortly to expose a portion of the roadway so that those interested might have an opportunity of viewing it.

INSTITUTION OF CIVIL ENGINEERS.—On Tuesday evening, M. Charles Bontemps, engineer in the French postal service, read a paper on "Experiments on the Movement of Air in Pneumatic Tubes." The establishment of the pneumatic system in Paris afforded the author an opportunity of investigating the movement of air in the tubes. For this purpose a system of registration was adopted, electric indicators, connected by wires with a chronograph, being placed at intervals along the experimental tube. Each indicator consisted of a box, containing two cams controlled by springs and a projecting stud. At the spot where the box was attached to the tube, a hole was drilled in the latter, and the box was placed in such a position that the stud entered the hole in the tube, its rounded end projecting slightly beyond the inner surface. The carrier in transit struck the stud, which actuated the cams, and the electric circuit being thereby closed, a mark was made upon the chronograph. This instrument consisted of a train of clockwork giving motion to a cylinder, round which was wrapped a sheet of smoked paper. Parallel to the axis of the cylinder there was a carriage bearing two electric magnets, one in connection with the indicator in the tube, and the other with a second-beating electric clock. Each armature was terminated by a fine point, which reproduced on the smoked paper the oscillations of the palette. Motion was given to the carriage by a cord and weight. The carrier, in passing along the tube, closed the circuit on striking the studs producing a deflection in the straight line traced by one point on the smoked paper. The other point produced a regular indented line parallel to the former, each indentation representing one second. These lines alternated with one another. As soon as the observation was taken the smoked paper was removed, and the surface was fixed by placing it in a solution of gum. The moment of commencing the experiment was electrically noted by a commutator attached to the cock between the reservoir and the tube. The experimental tube had a total length of 6701 feet 8 inches. It was made of wrought iron 2·52 inches in diameter, in lengths of 16 feet 4⅞ inches; and connected the central station at Rue de Grenelle, St. Germain, with that of the Place du Théâtre Français. From experiments the author deduced:—(1) That the time occupied by each piston in traversing the interval between two successive indicators closely approximated, which showed that the two pistons required similar periods to traverse similar distances. (2) That two pistons which had acquired their normal distance apart, preserved it throughout the whole journey. (3) That the progress of the carrier last introduced was independent of the initial position of the first. From No. 2 it followed that the density of the air was constant from the commencement to the end of the journey as soon as uniform movement in the tube was established.

[ME]CHANIC AND WORLD OF SCIENCE: No. 550.

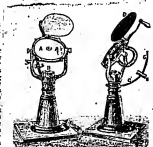
ARMY SIGNALLING.

[9771.]—I SEND a description with diagram of an invention of my brother in Australia, who has desired me to send it to you, as he thought it would be interesting to English readers. The account is taken from the *Sydney Mail.*

At a time when the attention of the public is constantly being directed to military matters, anything that relates to what may now be truly called the science of warfare will no doubt prove interesting to the readers of the ENGLISH MECHANIC. An instrument has lately been designed by Lieut. T. S. Parrott, Volunteer Engineer, New South Wales, proposed to be used for army signalling purposes. The annexed engravings show the front and side elevations of a sematrope, the name given to the instrument. It is an adaptation of the heliostat, or heliotrope, used in trigonometrical surveying operations, and is capable of being used with facility under moderately favourable conditions of atmosphere to a distance of about fifty miles, over which extent messages may be transmitted; and although such an instrument may be used in surveying operations, the peculiarity of its construction has been so regarded as to give the greatest possible facility to the transmission of telegraphic messages by means of the Morse or any similar system:—"The first point of difference between this instrument and the heliostat is in the reflecting medium employed, which is a mirror, the reflecting surface of which is an arc 4·5in., whose versed sine is ·01. The object of this curve is to save the difficulty arising from the apparent motion of the sun, which is constantly changing the direction of the reflected rays from the surface of the mirror. The effect of this curve is to disperse the rays to such an extent as will materially increase the length of time during which the flashes can be made without adjustment, and at the same time without reducing to any serious degree the brilliancy of the light. In signalling with a mirror it is a very essential point that it should be free from the slightest vibratory motion—in fact should be fixed perfectly steady, and remain so—during the process of flashing the signals. This object is attained by fixing the moveable portion of the instrument to a heavy cast-iron base, around the top of which the mirror is made to revolve, and to which it is firmly clamped when in position. Another feature peculiar to this instrument is in the lens tube for directing the rays, which has been so arranged as to work independently of the mirror; it is made to revolve around the upper part of the cast-iron base upon a curved arm, whose centre coincides with the centre of the mirror, to which point it is therefore always directed (the tube being fixed at right angles to a chord of this arc, on a sliding bar, which may be clamped in any position).

"The heliotrope was invented by Gauss (a celebrated German mathematician) about the year 1821, for the purpose of rendering the vertices of the triangle visible in the triangulation of the kingdom of Hanover. Captain Drummond, R.E., afterwards invented an instrument (called the heliostat) which was used with great success in the triangulation of Great Britain, and similar instruments have been used in geodetic operations in the United States of America and other countries.

"The Germans appear to have given the most attention to these instruments, and have at various times introduced improvements in their construction—improvements chiefly intended to overcome the difficulty of directing the reflected rays to any given remote point.



"The principal features of the sematrope which render it available for signalling purposes are:—

"1st. The convexity of the reflecting surface A, by which means the reflected rays of the sun are diverged, and will therefore be visible from a distant point for a much longer period of time than rays reflected from a plane surface.

"2nd. The lens tube B, for indicating the direction of the reflected rays, is so arranged that it may be adjusted without moving the mirror.

"3rd. The mirror may be adjusted without giving any motion to the arm C carrying the lens.

"4th. A moveable cover, D, to the mirror is provided, by means of which flashes of light may be shown in such a manner as to transmit messages by a system similar to that adopted in electro-telegraphy.

"In 'Chambers' Encyclopædia' the heliotrope is described as being used by surveyors for rendering distant stations distinctly visible. This is managed by placing a mirror at the distant station, and adjusting it so that at a particular hour of the day (arranged beforehand) the light of the sun shall be reflected from the mirror directly to the surveyor's station.

"The surveyor must make his observation almost at the instant he sees the glancing of the mirror, as the constant change of the sun's position in the heavens produces a corresponding change in the direction of the rays reflected by the mirror. Gauss invented such an instrument about 1821, which is used abroad, especially in America, for geodetic surveys, and is said to possess such power that a mirror 1in. square is visible 8 miles off in average sunny weather, and appears as a brilliant star at a distance of 2 miles; while some heliotropes have been used so powerful as to be visible nearly 8[?] miles off.

"The term heliostat, applied by Captain Drummond to an instrument invented by him for the same purpose, more properly belongs to an instrument invented by S. Gravesande, consisting of an equatorial ... revolving on its polar axis, so that the sun, w... once accurately in the focus of the telescope, ... tinues steadily fixed there.

"Recent experiments have been made with ... sematrope by Mr. Parrott, which have proved ... capability of performing the work for which it wa[s] designed."

Lieutenant Parrott has also made experiments with his instrument by the light of the moon, and succeeded in flashing messages over a distance of 8 miles.

Frank Parrott.

8

The Heliograph of Mr. Mance.*

BY C. BECKER.

Though the general introduction of Electric Telegraphy, and the all but universal adoption of the Morse alphabet, it occurred to Mr. Mance—who has the advantage of a thorough knowledge of both, and the privilege, if it can be called one, of a long residence in a country with plenty of sunshine—to develop and improve the existing appliances into a system. His aim has been to produce an instrument which is very compact, very portable, easily set up, and easily worked. Although he was first in favor of larger instruments (which are still preferable for permanent stations), he is now convinced that an instrument of the size here shown is all that is requisite. The chief objection to the adoption of the sun-telegraph is, that we cannot command the sun to shine in the same manner that we can control a galvanic battery; and it must be understood that Mr. Mance advocates his system only as an auxiliary to other systems of field telegraphy. It would come into operation at distances when other methods are useless or tediously slow, and it compares favorably with existing systems of signaling in cheapness, range, rapidity of communication, and, last, in portability. The flashes are invisible to any one placed far to the right or left of the direct line, so that, from elevated points, far distant communications could be kept up with a fortress without the besiegers having any suspicion of the fact.

It would be superfluous to give instances, when within the last few years the use of these instruments might have brought about the most important results.

The instrument consists of a light, but firm, tripod-stand, similar to those used for prismatic compasses. On the top a plate is moved by a tangent screw which admits of quick and slow motion, and the plate carries on a pin a semicircular ring, which again carries on pivots the round mirror, the silvering of which is removed in the center for the space of a circle about 3-16th inch diameter. To the plate is also attached a simple key, which is pressed down and springs back like an ordinary Morse key. This key is connected with the top rim of the mirror by a steel rod, which can be lengthened and shortened—as occasion may require—by turning the handle and screwing the rod through the small brass ball which secures it to the edge of the mirror.

By means of the last-named adjustment and the tangent-screw the glass can be altered, as the ever-changing position of the sun may require.

From 12 to 15 yards in front of the instrument is placed a sighting-rod. This rod is to mark a spot exactly in a line with the center of the heliograph and the distant station. A metal stud marks the spot, and a wooden cross-piece marks where the flash rests when not directed on the opposite station.

The instrument can be set up ready for working in a few minutes. When the exact position of the distant station is not known, a flash of sunlight must be thrown in the direction of the most likely points, and this must be continued till it is answered by a flash, which indicates that a distant signalling party is on the look-out. Then, after releasing the tangent-screw, the glass must be turned to a convenient angle, and the sightingstick must be directed in a line with the distant station by looking through the small aperture in the center of the mirror. When this is effected, the stud must be raised or lowered till it is in the line of vision on a level with the center of the glass and the distant flash, and the short cross-piece must be placed at right angles to the upright, about a foot below the stud. After being thus adjusted the instrument must not be moved.

The spot will be observed gradually to rise or fall, according to the direction in which the sun is apparently moving. The handle of the key, or the tangent screw, or both, as the case may be, must be turned slightly after every two or three words, to insure, as far as possible, that the center of the spot shall be on the stud when the key is pressed down.

When the sun is rather low in the heavens, and behind the signaller, it becomes more difficult to direct the flash with accuracy. In consequence of the obtuseness of the angle the spot loses its circular form, and becomes rather dim when reflected on the stick. If it is required to work frequently with the sun in this position, the employment of a second glass on a light tripod stand is recommended.

But it would be useless here to enter more into the minutiæ of working the instrument: suffice it to say that, in experienced hands, twelve words and more per minute have been obtained, while others state that men—after a fortnight's practice—could attain only from four to five words per minute. As to the distance, 10 and 20 miles—and in very clear weather 40 miles—have been obtained.

A number of officers of the Indian Army have tried and reported upon the instrument, and—with the exception of one—all report most favorably of the system as an auxiliary to existing systems, and efforts are being made at the present moment to insure their adoption for the Indian Service by the authorities.

Engineer Mch 19
1881

ACCORDING to the census lately taken, the population of the German Empire is now 45,194,172 persons.

DURING a hailstorm in Geneva on January 19th, Prof. Colladon observed the hailstones as they fell repel each other mutually and to bound about after lying quiet for a moment or two on the ground exactly after the fashion of the pith balls in the well-known experiment of the electric hail. The observation, says *Nature*, would appear to have a bearing on Volta's somewhat neglected theory of the formation of hail.

PNEUMATIC TRANSMISSION.—No. VII.

AFTER the various experiments already recorded, the utilisation of water in turbines was tried. The air is compressed or expanded by means of pumps, and the object of these trials was to take advantage of regulators to reduce the cost of water in proportion to the work to be done. It is well known that the operation of compression or expansion involves a constantly varying amount of work. In forcing a cube foot of air into a receiver the effort required increases with the increasing pressure in the receiver, and inversely the work performed in taking out a foot of air from a reservoir increases as the pressure in that reservoir diminishes. This is a condition which has not been taken into consideration in the processes already described. As at the conclusion of the process of compression by displacement, it is the same quantity of water that is necessary to introduce a foot of air into the reservoir; there is consequently the same amount of work expended, although in this interval the resistance to be overcome may have increased. Induction combined with displacement partially makes up this loss of power. In utilising the fall of water to produce a vacuum for giving motion to the trains, the water is displaced by the air in the line, and for each foot of water that falls the quantity of air extracted continues to diminish from the commencement to the end of the discharge.

The turbine regulator conforms to the variations in speed, it reduces or increases the sectional area of the conduit which conveys the water, and produces in the speed of the motive power variations corresponding to that of the pumps.

With the turbines the duty in compression or expansion will reach about 50 per cent. (of which about half is absorbed by the pumps and half by the turbine). Reducing this result to compare the cost per journey on this system with the three preceding ones we find:

1. In the case of compression. The journey is made by means of air that has a pressure above the atmosphere of 17.716 in. of mercury at the commencement, and a quarter of an atmosphere at the end. The capacity of the air reservoir for a line one mile in length is 639.12 cub. ft. To raise 639.120 cubic feet from the pressures equivalent to 29.921 + 7.48 in. of mercury to 29.921 + 17.710 in. it is necessary to deal with a capacity of air equal at atmospheric pressure to 236 cubic feet. The work necessary to force these 236 feet of air into the reservoir at the mean pressure of $\frac{17.71+7.48}{2}=$ 12.60 in. will be found by calculation to be equal to 173,170 foot-pounds, which represents the useful work of the pumps driven by the turbines, assuming that the duty is 50 per cent. as above stated, which would give a total force to be developed by the turbine of 173,170 × 2 = 346,340 foot-pounds, and a volume of water under a head of 36 ft. of about 154 cubic feet. The price of water being

... cubic feet, and that consequently the cost of ...er journey is reduced to 18.24 × .1055 = 1.924d. ...application of turbines for the compression ...thus realises a very marked economy. MACHINE-MADE ELECTRICITY.

Its Test in the Western Union Main Office for Telegraph Purposes.

The substitution of dynamo-electric machines by the Western Union Telegraph Company in its New York main office for the chemical batteries has given such good satisfaction that the most of the old batteries, though still in place, have been cleaned up. None of these batteries has been in use for several months, except for short wires inside of the city. The last of the wires radiating from New York to be operated by machine-made electricity were the quadruplex lines, the longest of which are to New Orleans and to North Sidney, in Cape Breton, the terminus of the Anglo-American cable. The use of the machines, although there is little doubt it will be continued, is yet declared to be only in its experimental stages.

All the electricity used on lines running out of New York comes from two banks of machines, each bank run by a small engine of about ten-horse power. There are five machines in each bank. One of the five machines merely furnishes electricity to convert the bent soft iron bars of the other four machines into magnets, so that, in fact, each bank has only four machines for the distribution of electricity to the company's wires. Each machine is the same in principle as those used for producing electric lights, that is to say, a bobbin wound from end to end with insulated wire is made to revolve near a magnet. A current is thus formed in the wire wound about the magnet. In one of the banks of machines the bobbins are turned one way, producing positive electricity, and in the other bank they are turned the other way to produce negative electricity. Both kinds are required to meet the requirements of different offices.

The power of electricity to perform telegraphic work is called its potential, and the potential is reckoned in volts. The company gets from the first machine in the bank a potential of about seventy volts, that is to say, the equivalent of seventy cups of the Callaud battery formerly in use for main lines. A wire leads from this machine to convey electricity to those lines that require only seventy volts to operate them. There is a connection between the armature of the first machine and that of the second, at the further end of which a second wire leads to the switchboard. Its potential is about 130 volts, and it supplies lines requiring so much potential. There is an increase of potential in each machine, but it is not necessarily doubled each time, since the potential depends not only upon the rapidity with which the bobbin is geared to run, and the strength of the magnet, but on the amount of resistance. From the fourth machine is obtained a potential of about 310 volts, which is used only on the Chicago, New Orleans, and long quadruplex lines.

In case either of the two banks mentioned needs repair a third bank, run by a separate engine, may be put in use to supply either positive or negative electricity. First the new bank is set in motion and its electricity is put upon the lines which carry a double supply for a moment until the other bank is stopped. The effect on the lines is not noticeable, because, although the quantity of electricity is increased, the potential is the same.

The difference between quantity and potential is illustrated by electricians as follows: If a drop of water is closely confined and heated, it will develop a violently explosive force; but it would be instantly exhausted. On the other hand, the steam from a boiler, although by no means so hot, may be drawn off in a continuous jet. It is also said, by way of illustration, that there is not a sufficient quantity of electricity in a whole thunder storm to run a single line of telegraph, but what there is there has a terrific potential. Potential gives working power. Quantity enables the electrician to feed many lines.

There is a very low resistance in these machines, or, in other words, the electricity produced finds an easy channel. For this reason the current is supplied to each line through a resistance coil of German silver wire wound around a chalk cylinder, which furnishes a definite amount of resistance. Otherwise an accidental short-circuiting on one line might divert from all the other wires the current necessary to work it.

The company has put machines into its New York office only. In one sense they are not so much under control as the old batteries. In the case of the batteries just as many cups as might be desirable to work a line could be used. Now the electrician, if seventy volts is not enough to work a line, must tap the second machine and get double the number of volts. He cannot get any intermediate number. The machines are found to be cheaper by nearly one-half than the chemical batteries were. They take less space, and are more easily taken care of.

The Heliograph.

The London *Daily News* states that they have to thank the heliograph again for an important message received from General Stewart, and announcing the result of an attack on the British troops, in which the enemy seem to have suffered severely. The message is dated Camp Ghuzni, April 22, and was received at the India Office the following day. It is very probable that the news could not have been brought so speedily by electric telegraph. The heliograph does not require the route to be kept open. The line of communication cannot be cut, for the simple reason that the signaling takes place over the heads of the enemy, and the stations required are but few and far between. A ten inch mirror, and this is the diameter of the ordinary field heliograph, is capable of reflecting the sun's rays in the form of a bright spot, or flare, to a distance of fifty miles, the signal at this interval being recognizable without the aid of a glass. That is to say, two trained sappers, each provided with a mirror, can readily speak to one another, supposing the sun is shining, with an interval of fifty miles between them, provided their stations are sufficiently high and no rising ground intervenes to stop the rays. The adjustment of the military heliograph is a very simple matter. An army leaves its base where a heliograph station is located, and after traveling some miles desires to communicate with the stay-at-homes. A hill in the locality is chosen, and a sapper ascends with his heliograph, which is simply a stand bearing a mirror swung like the ordinary toilet looking glass, except that besides swinging horizontally it is also pivoted so as to move vertically as well. Behind the mirror, in the very center, a little of the quicksilver has been removed, so that the sapper can go behind his instrument and look through a tiny hole in it toward the station he desires to signal. Having sighted the station by adjusting the mirror, he next proceeds to set up in front of the heliograph a rod, and upon this rod is a movable stud. This stud is manipulated like the foresight of a rifle, and the sapper again, standing behind his instrument, directs the adjustment of this stud until the hole in the mirror, the stud, and the distant station are in a line. The heliograph is then ready to work, and in order to flash signals so that they may be seen at a distance, the sapper has only to take care that his mirror reflects the sunshine on the stud just in front of him.

* Papers read before Physical Society.

should not exceed 27.16 in. Under these conditions the cubic capacity of the reservoir should equal 491.5 cu. ft. This reservoir being originally full of air at atmospheric pressure, the amount abstracted by means of the pumps will be at each stroke of the piston, equal to the capacity of the pump barrel (the pressure being the same as that in the reservoir).

The mean pressure in the reservoir is

$$\frac{29.921+15.748}{2}=22.834 \text{ in.}$$

To reduce the pressure in the reservoir from that of the atmosphere to 15.748 in., it is necessary to withdraw a capacity of air at the average pressure equal to

$$491.5\times\frac{29.921-15.748}{22.834}.$$

The work to be performed by the pumps is the difference between the work at atmospheric pressure equal to 29.921 in., and that at the mean pressure 22.834 in. Its equivalent is the product of the volume, $491.5\times\frac{29.921-15.748}{22.834}$, by the difference $(29.921-22.834)=7.087$ in. of mercury, which converted into equivalents of water represents 23.35 in. On making the calculation it will be found that the amount of useful work of the turbine is equal to about 153,000 foot-pounds, which corresponds to the power developed by the water used of 306,000 foot-pounds, representing a quantity of water with a fall of 52.5 ft. equal to $\frac{306,000}{52.5\times62.5}=$ 93.28 cubic feet. The cost of a journey under these conditions would be, therefore, 1.7d.

The arrangement of the double-acting pump adapted is shown in Figs. 86 and 87, on the opposite page. One of the barrels A supplies the compressed air, and the other A_1 exhausts the reservoir; this action being produced by the suction valves $a\,a^1$ and the delivery valves $p\,p^1$. These latter admit the compressed air to the reservoir, and the former exhaust the air from the vacuum reservoir. The other valves $a\,a^1$, $p\,p^1$, are in communication with the atmosphere. The pistons P, P_1 are fitted with gun-metal rings, and motion is given to them through the crosshead $t\,u\,v\,x$, and the connecting rods $m\,n\,p\,q$, which are actuated by the turbine. This system is employed for working a post like Fig. 47 (see page 353 of our last volume). The dimensions of the whole apparatus are such that they can exhaust the air to give motion to the trains on the section 7-10 (.621 mile long) and compress it for working the similar sections 10-9 and 9-8.

The pumps make 22 strokes per minute, and the respective volumes A and A_1 are 2318 and 1801 cubic inches. Proper means are provided for keeping the pumps well supplied with water. In the turbines employed the number of openings for receiving the water can be varied according to the work to be done, by means of a centrifugal regulator. We may now give a description of Fig. 88. The water enters the turbine by the passage O and is spread by means of the directrices M upon the wheel N, which is thus caused to revolve together with the shaft $y\,z$. With a fall of 39 ft. 6 in. a turbine of this pattern $23\frac{5}{8}$ in. in diameter makes 245 revolutions per minute, and discharges 1.72 cubic feet of water per second when ten openings are supplied, which is the maximum number in this type. The speed of 245 revolutions per minute is reduced down to 22 before it reaches the pumps by the gearing $a\,b\,c\,d$. To the last wheel d are attached the connecting rods $p\,q$ of the pump.

The regulator R receives motion by means of the wheel b_1 in accordance to the variation in the speed, and turns the wheel l either in one direction or the other, by means of the bevel wheels f and f_1. The motion of the wheel l determines the advance or recession of the covering plate d, which opens a greater or less number of orifices.

It will now be expedient to group the various details together into their proper positions, in order to give a clear idea of a station. Figs. 89 and 90 on the opposite page are plans of the floors of a station in which the method of working by compression and exhaustion by means of turbines is employed for three sections, 7-10, 10-9, and 9-8. The station is situated at point No. 10, Fig. 47, see page 353 of our last volume.

The basement contains the turbines T, the pumps B, and the pressure and vacuum reservoir C and D respectively, with the necessary connecting pipes.

On the ground floor, Fig. 90, are the receiving apparatus E and F connected with the lines 7-10 and 10-9; the rarefied or compressed air is conducted by special pipes.

The drawing shows two turbines and two pairs of pumps, as the station is designed for a continued service, and it is necessary to have the second in readiness whilst repairs are being executed.

Finally, in order to work the transmitting apparatus, transmission shafts control the cocks placed in the feeding pipes. It is sufficient to close or open these cocks to stop or start the pumps for compression or exhaust, according to circumstances.

The water of the Ourcq has not an equal pressure throughout Paris. When the level of the station is as high as that of the basin of Villette, which is fed by this river, it is necessary to abandon the use of water, or rather other water may be utilised (for example, that of the Seine, Dhuys, &c.), but the cost is doubled at least. It is, therefore, necessary to make use of steam power, which is inconvenient of application in the crowded portions of the city.

We here make a new step in the direction of economy, for it will be easy to show that it is cheaper to employ steam for driving pumps arranged as just explained, than water. Using again the same data as before, the work necessary for compressing the air required for one journey is 173,170 foot-pounds. The time assumed for the journey being 15 minutes, the work to be performed by the machine is equivalent to .35 horse power.

The proportion of useful work given out by the pumps may be taken at 70 per cent., so that the actual power required would be .50 of a horse power to compress the air required for one journey.

The consumption of coal per horse power per hour may be assumed as 6 lb., and this would only show a cost of .14 pence per journey.

But the cost of coal is not the only one to be considered in this calculation. Additional labour is involved, the value of water, oil, &c., must be also be included, and indeed the cost of the coal may be assumed as one-third or one-quarter of the total outlay. Taking this latter proportion, we shall have the result of

$$.14\times4=.56\text{d.} \qquad . \quad . \quad . \quad (6)$$

as compared with the result previously obtained by the other methods—the turbine, and displacement, simple or modified.

Referring only to the cost (4) which refers to compression with turbines working under a head of 52.5 ft., we find that steam power costs 2.5 times less than that derived from the water of the Ourcq, utilised in the best possible manner.*

We indicate the two principal methods of working by compression or exhaustion in the illustrations on page 88. The upper figure shows the general arrangement of the station in the Place de la Bourse, in which are placed seven vertical receiving and distributing apparatus. Two reservoirs in communication with the water mains producing the compressed air by displacement in the accumulators are placed in the basement of the station.

The lower figure shows the arrangement of the central station Rue de Grenelle, St. Germain, with horizontal receiving apparatus, and pumps worked by a six-horse portable engine. With this power, trains are worked over nearly 9 miles of line, the intervals between each being 15 minutes.

The receiving apparatus in reality occupy two different parts of the stations, they have, however, been grouped together that they may be seen in the drawing.

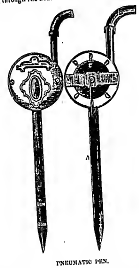
* In all the calculations that we have thus successively presented for estimating the comparative cost of working, no account has been taken of first establishment charges, or of amortization.

The Mance heliograph, an optical telegraph apparatus, has been recently tried for telegraphic purposes across the Straits of Gibraltar, from Algesiras to Ceuta, a distance of seventeen miles. The rate of transmission is about half that of the Morse. When a new "heliograph" for night signalling and cloudy days is completed, the system will be adopted, as it is found difficult to maintain the ordinary submarine cables across the Straits.

14

PNEUMATIC PEN.

Among the many attempts of inventors to supply a ready means of copying an indefinite number of writings, drawings, etc., is the apparatus shown in sketch, which, apart from the question of utility, is at least simple and ingenious. The pneumatic pen, as it is called, is not new in principle, as a perforating machine, acting in a similar way, has been in use by embroidery manufacturers for many years, and all that the inventor of this apparatus has done is to arrange the whole thing in such a simple way that it can be as readily used as an ordinary pen. The tube A in the illustration contains the needle B, which is connected to a crank on the axis of the fan-wheel C. Rapid motion is imparted to the fan by means of a blast of air either from the mouth of the writer or on air-bellows, through the flexible rubber tube D, connected with a



PNEUMATIC PEN.

foot-bellows or blown from the mouth of the operator. On moving the point of the pen over a sheet of paper, it becomes pierced with very fine holes in lines of the desired pattern. Ink or color is then spread over the surface which fills the holes, and passes through the stencil to as many sheets of paper as may be brought in contact with it. Originals may, it is stated, be multiplied in this way at the rate of 300 per hour. —*Eng. Mechanic.*

Dec. 76

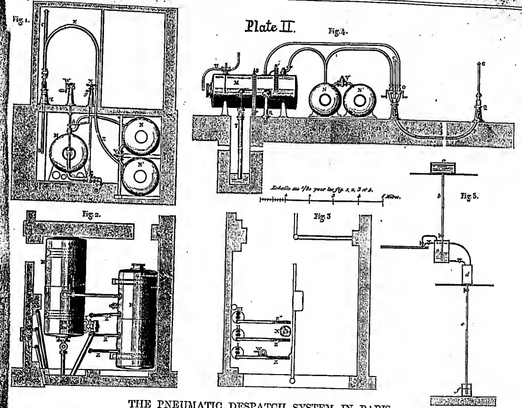
The Western Union Telegraph Company are laying down two pneumatic tubes and underground wires in New York, between the main office, corner of Broadway and Dey-street, to No. 14, Broad-street office. Two tubes will also be laid from the main office to 134, Pearl-street, and the Cotton Exchange offices. June '76

The pneumatic tubes will be of brass, which has been decided upon as preferable to lead or iron for this purpose. The carrier is a gutta percha pouch or box, covered with felt, two inches in diameter, with a band of felt projecting around the ends. Each carrier has a capacity for 50 messages, which are kept in place by a rubber band.

Duplex engines (working both by compressed and exhaust air) are to be used to force the boxes through the tubes, by means of which boxes will be sent in alternate directions through the pipes. The pistons of the pumps have an internal diameter of over two feet.

Subterranean wires will also be laid over the same routes, in cast iron pipes three inches in diameter, and which will be capable of containing 125 wires each.

The work is being carried out under the superintendence of Mr. George B. Prescott, the electrician to the Company, who came to Europe two years ago to examine the various systems employed in England and the Continent.



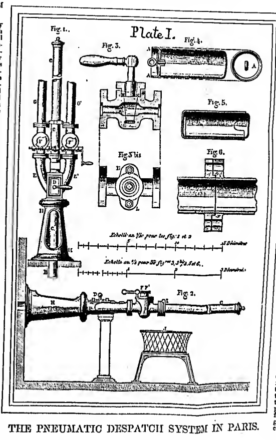
THE PNEUMATIC DESPATCH SYSTEM IN PARIS.

THE PNEUMATIC DESPATCH SYSTEM IN PARIS.

Paris at the present time is traversed by about thirteen miles of tubes, through which messages are transmitted between nearly all principal localities in the city by pneumatic pressure. Paradoxical as it may appear, the rapidity with which despatches may by this means be sent between short distances exceeds that of the telegraph, when the number of distinct despatches which it is possible to transmit in a given time is taken into consideration. Forty messages of one hundred fifty words each per hour is about as rapid as can ordinarily be accomplished on a single wire, allowance being made for the necessary writing out of the despatches, etc. By the pneumatic tube connecting with the Bourse, stock quotations are forwarded to various parts of the city at the rate of 8000 per hour, it being possible to start twenty trains of boxes containing four hundred written despatches each in that period of time.

The apparatus employed, invented by MM. Crespin and Rouart, is extremely simple, and may be understood from the annexed engravings, extracted from the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale.* The tubes are of a uniform diameter of 2.6 inches, and are drawn of wrought iron. The joint which connects the sections is represented in Fig. 6, Plate I., and is rendered tight by a thin sheet of india-rubber placed between the partitions. These connections are placed at distances of about 25 feet apart. The carriages used are of two kinds: those which receive the pneumatic pressure, and so are forced through the tubes; and those which make up the train, which is drawn by the former, and in which the written messages are directly deposited. The first are hollow cylindrical boxes of wood or metal (Fig. 4, Plate I.), and to the rear of each is secured a leather-flanged disk, which packs itself against the interior of the tube when impelled by the blast. The other carriages are of metal, covered with leather, and resemble in shape and form small cigar-cases (Fig. 5, Plate I.). They are about 4 in. less in diameter than the tube, and simply glide along its interior when drawn by the pulling carriages above mentioned. The speed of the train is some 30 miles per hour, under a total pressure in the tube of from 44 to 55 lbs.

The principle of the apparatus, by which air is compressed in rear of the carriages, or a vacuum formed in advance of them, either or both of which means of propulsion can be used at will, is exhibited in Fig. 5, Plate II. *a* is an air-tight reservoir, connected by the pipe *b* with the elevated receptacle *c*. In the latter water enters from the city mains, and, descending with a pressure proportionate to the head, enters *a*, and compresses the air



THE PNEUMATIC DESPATCH SYSTEM IN PARIS.

therein until an equilibrium of pressure ensues. If *a* contain one cubic foot of air, for example and the water enters to fill half its volume, the air then will be under a pressure of two atmospheres, and may be led off by pipes to perform its work. A reverse process produces the vacuum. The water already in *a* is led into the chamber *d*, whence a tube, *e*, descends to a chamber situated more than 32 ft. below. *d* being full of water, and communication being opened through *e* and shut from *a*, it is obvious that a water barometer will be formed and the water descending in *e* will leave nearly a perfect vacuum in *d*. It remains only to shut the cock in *e* and open connection through the pneumatic tubes when the normal air pressure in rear of the carriages will impel them.

The starting and receiving apparatus, which are identical, and may be placed *either* vertically or horizontally, are shown in Figs. 1 and 2, Plate I. B is the message tube, terminating in a vertical portion C, on which is an iron box D, having a door which may be hermetically closed. From said box extend branch tubes, EE', in which are placed valves or cocks, operated by the toothed sectors FF', and the endless screw and crank shown. The arrangement of these valves is such that when one is opened the other is closed, and *vice versa*, the single crank operating both at once. The train of carriages is dropped through the box D into the tube C, the door is closed, and if compressed air is to be used, the handle is turned so as to admit the pressure, for example from tube E; the other tube, which opens into the atmosphere, is necessarily then closed. If a vacuum is to be employed, the crank is turned so as to reverse the valves, the compressed air being shut off, and that of the atmosphere allowed to enter.

When the carriages reach their destination, they pass the box D, where the compressed air finds an exit, and shoot into the prolongation C. By compressing the air before them they form an air cushion, which checks their momentum without shock, and they rebound. They then may be removed at D, or may be allowed to accumulate in C, which is hinged at I, Fig. 2, so as to be opened when desired for their removal. Electric communication between stations gives warning of the departure of trains, etc.

The air-compressing and vacuum apparatus actually in use is exhibited in plan Figs. 2 and 3, and end and side elevations in Figs. 1 and 4, Plate II. M is the water chamber, and N N (two cylinders being employed for economy of room) are the air or vacuum chambers. O is the transmitting apparatus, P the tube, and Q the receiver. R is the water pipe leading from the city mains, the water from which compresses air in M, which air is then drawn off for use into the cylinders N N. S is a water-gauge to show the water level within. The chamber M may also be used as a vacuum

1876

M. Henri C. Mance a imaginé un héliographe avec manipulation du système Morse. Il se compose d'un petit miroir qui réfléchit les rayons solaires et dont le rayon est perceptible, avec une bonne orientation, jusqu'à une distance de 80 kilomètres. La manipulation consiste à faire frapper le miroir contre une vis qui fixe le point d'orientation, de la même manière que l'on manœuvre un levier Morse. Beaucoup plus simple dans son mécanisme et dans son réglage que les appareils héliographiques déjà imaginés (notamment celui de M. Lesseurre qui a été expérimenté et, dans certaines circonstances, appliqué en Algérie à des distances de 30 à 40 kilom. [1]), l'héliographe de Mance est comme l'héliographe Lesseurre, basé sur une combinaison de rayons de longue et de courte durée, correspondants aux traits et aux points de l'appareil Morse. La difficulté pratique, pour des distances un peu considérables, consistera toujours dans la recherche du point de l'horizon vers lequel doit être cherchée l'orientation et, cette première opération une fois faite pour être découvert du correspondant, dans le maintien rigoureux d'une exactitude presque mathématique de l'orientation, la moindre petite déviation ayant tout de suite pour effet d'écarter de beaucoup les rayons réfléchis, du champ d'observation du poste correspondant. Pendant la nuit, l'on peut recourir à une source de lumière artificielle, mais son éclat plus faible ne saurait naturellement être réfléchi par le miroir à d'aussi grandes distances.

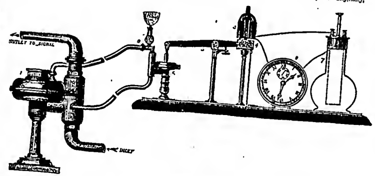
FLASH-SIGNALS.

By D. Bruce Peebles.

The apparatus consists of an ordinary gas-governor (1)—the one we have here is a dry governer, but it may be either of the wet or dry kind; it is entirely inclosed—and a small controlling governor (2) arranged to throw the pressure of the inlet gas upon the bell or diaphragm of the larger or supply governor, thus opening the valve. A small stream of the inlet gas flows into and out of the diaphragm, or bell chamber, and may be let away through an orifice, either into the main outlet or by a separate outlet-pipe, thus



PEEBLES' ELECTRIC FLASH-SIGNALLING APPARATUS FOR LIGHTHOUSES, RAILWAYS, ETC.

allowing the governor to be easily controlled, and weights being put on or taken off, the small governor opens or closes the valve of the large one.

The small governor (2) is loaded to give a supply of gas just sufficient to keep the burners lighted, or this may be done by means of a by-pass, with regulating stopcock; and a separate weight, sufficient to give a maximum supply of gas, is connected to one end of a lever (3), the other end of which is fitted with an armature (4) in a position to be acted on by a small electro-magnet (5). When the electric circuit is closed, the magnet causes the lever to lower the weight on to the small governor diaphragm and open the valve; but the weight is suspended from the lever by a loose link (6), so that only the pressure of the weight acts upon the governor. When the electric circuit is broken, the lever, having its armature end sufficiently heavy, lifts up the weight from the governor, and closes the valve. We see, therefore, that the small governor acts on the large one, by loading or unloading the bell or diaphragm with pressure instead of weights; and this principle may be modified and carried out in several ways. The electro-magnetic action is got from a small bichromate battery (7), and the small timepiece (8), which makes and breaks contact, is arranged to give six flashes each minute—but any other reasonable number of flashes can be given, if required—while 1,000 lights can be

as easily acted on as the seven we have here. For lighthouse purposes, or wherever a timepiece is employed to work the apparatus, it may be considered preferable to dispense with electricity, and place the lever (3) in a position, so that it may be acted on directly by the clock, and this can readily be done by a simple mechanical arrangement, as a very small amount of power is required to lift the lever and lower the weight on to the small governor. We now put the apparatus in action, and it will be observed that the flashes are given with a precision that leaves nothing to be desired. It will be readily understood that, while the rapidity of the flashes can be greatly increased, the duration of the flash can be prolonged, if necessary. The small current of controlling gas may either flow into the main outlet-pipe, or into a separate pipe, as before stated; but it is advantageous in this case to make the outflow pass through the small orifice by a separate pipe (9), as by increasing or diminishing the size of the orifice the flash may be made sharp or sluggish, as wished, without in any way altering the pressure of the gas supplying the signal-lights.

This method of flash-signals may also be applied to railways, and a train may be made to give a visible signal of its approach at any distance from the station. A powerful gas-light might be placed at any central point which could easily be seen from any part of the station where the train is expected, and it would only be necessary to get the wheels of the engine or carriages at a mile or two miles distant, as the case might be, to touch a spring, make contact, and close the circuit, when the light would at once flash forth at full power, warning those at the station that the train was approaching. The light could either be allowed to go down after the train had passed the contact spring, or remain as a signal until some of the officials at the station released the catch-pin, thus letting the gas down again to a minimum.

The system might also be used for giving a visible time-signal all over a city, say, at nine o'clock every night, so that in every house in which gas is used, the time could be obtained by noticing the gas-flame, which would be lowered for a second or two at the particular hour agreed upon. This could easily be done by acting on the station-governor at the gas works, and correct time would be insured by using one of Mr. Frederic Ritchie's regulated clocks, a number of which are now in use in Edinburgh and other places.

It seems well adapted also for Professor Jenkins and Sir Wm. Thomson's system of eclipse signalling by the Morse alphabet, the dot and dash being represented by long and short period of darkness.

A method of balloon signalling might also be established wherever a supply of gas could be obtained. The balloon would carry up flexible gas-tubes, and the flame would be protected by a lantern and wind-guard. In such a case, if used for war purposes, a cypher would be fixed on for giving the messages, and the gas might be compressed and transported to any suitable place for giving the signals.

There is yet another purpose it might be applied to. A small apparatus of this sort might be attached to the gas-pipe of any licensed houses whose landlords were suspected of setting Forbes Mackenzie at defiance. It would, in such a case, be set to turn off the gas at eleven o'clock P.M., and put it on again, say at six A.M. The authorities would only have to see that the clock and battery were attended to once a week, and might then rest assured that, so far as gas was concerned, no supply would be had after the legal hour of closing.

Lastly, it could be attached to the station-governor of any gas-works, and adjusted so as to give the day and night pressure at any hours the manager wished, so that, if all of us here who have station-governors had also a controlling apparatus such as this, we might have set it before leaving home to-day, with a certainty that the night pressure would be put on in our absence at the exact hour we arranged the timepiece to make contact.—*Journal of Gas Lighting.*

Berlin Pneumatic Despatch.—The proposed pneumatic despatch line in Berlin will have 26 kilometers of tube, and 15 initial stations. The wrought iron tubes have a clear breadth of 65 millimeters, and lie about one meter below the surface of the ground. The letters and cards which are to be forwarded have a prescribed size, and are enclosed in iron boxes, or cartridges, each of which can hold 20 letters or cards. In order that they may pack closely, they are covered with leather. From 10 to 15 cartridges are packed and forwarded at a time; behind the last cartridge is placed a box with a leather ruffle, in order to secure the best possible closure of the tube. At four of the stations are the machines and apparatus needed for the business. The forwarding of the boxes is effected either through compressed or rarefied air, or through a combination of the two. Steam engines of about 12 horse power are used for the condensation or exhaustion of the air. Each main station has two engines, which drive a compressing and an exhausting apparatus, the steam for each engine being furnished by two boilers. Large reservoirs are employed both for the condensed and for the rarefied air. The former has a tension of about three atmospheres; the latter, of about 35 millimeters of mercury. The air, which is heated to 43° C. by the compression, is cooled again in double-walled cylinders which are surrounded by water. The boxes travel at 1,000 meters per minute; a train is despatched every 15 minutes. Each circuit is traversed in 20 minutes, including stoppages. The cost of the enterprise will be about $300,000.

Aug 77

Telegraphers' Paralysis.—This peculiar nervous affection is causing some alarm at present amongst operators in America, where it appears to be unusually prevalent. It is a numbness and paralysis which affects the thumb, hand, wrist, and even forearm of the operator's right or keying hand, and positive pain is felt in attempting to handle the key when afflicted by it. It is unquestionably due to overstraining of the nerves and muscles in the rapid, minute, and monotonous motions of signalling; and is generally cured by rest. Its greater frequency in America than in Europe seems to be due to the "space" letters of their alphabet, and perhaps to the longer hours that American operators remain on duty. It appears to us that the happy mixture of dots and dashes, long and short signals in the Morse code, as it is used in England and the Continent, is calculated to prevent paralysis, for every dash is a brief rest to the hand. The matter has become so serious in America that there is a talk of introducing a a new code to replace the Morse as there practised. It would certainly be a safeguard against paralysis if every operator would learn to signal, at least moderately fast, with his left hand as well as his right. He could then occasionally rest the right, and perhaps, more expert hand, thus giving it time to recover its full vigour before any over-stressing had taken place. This disease in question excited some discussion in England several years ago, but it appears to have died out of late, since we now hear nothing of it. We should be glad to receive any information on the subject from English clerks, or others, who have it to give, for it may prove useful to American telegraphers. Have the Post Office hours of duty anything to do with its apparent disappearance from among us?

PNEUMATIC POSTAL TRANSMISSION.

To the public works of large cities of the present day belong not only gas and water pipes, street railroads, electric telegraphs, but also the pneumatic mail connections, or "letter tubes," as they may be called. The electric telegraph requires short messages, and a certain time in condensing them, while the pneumatic mail overcomes all that. The same is not obliged to travel over the surface of the earth, as the tubes are placed subterranean, like the gas and water pipes, and within these tubes run, with a velocity of at least 20 meters in a second, the letters inclosed in boxes.

The whole system rests on the principle of the child's toy, in which, through a quill, peas are propelled in forward or backward directions. The function of the lips is taken up by a steam engine, which forms "vacuum reservoirs" by withdrawing all the air therefrom, and "pressure reservoirs" for the compressed air.

The engine of the Vienna Pneumatic Post Office has 20 horse-power. On the stations is a tubular apparatus, as shown in Fig. 2 of our illustration. An electric telegraph connects the stations to give the signals. Letters may be sent at a certain price and up to a certain weight. The letters are placed into a cylindrical box that fits exactly into the interior of the conducting tubes. Back of one or more such boxes is placed a piston that is fitted by leather packing rings tightly into the conducting tubes, and receives directly the pressure of the air from the air reservoirs. On the main station the engine works directly; on the intermediate stations the iron reservoirs, which are filled and emptied thereby. On the receiving station are means to admit the air so as to retard the speed of the boxes, while brakes and buffers prevent too heavy concussions.

The terminals of the conducting tubes are of polished brass, and resemble somewhat large trombones. The subterranean tubes are sometimes heated up by the friction of the air and boxes, and have to be cooled by water, which is forced out again by the air-pressure as soon as its object is accomplished. Sharp curves have to be avoided. The system of tubes may also be extended into private and business houses, so as to bring them in communication with one of the stations. In Vienna the system has been successfully worked since March 1, 1875, without any trouble or interruption. The large illustration represents the interior of a main and branch station, of the engine, of the air-compressors, and of the receiving and sending boxes, tubes, etc., of the Vienna Pneumatic Post Office; while the second illustration shows the interior arrangement of a Berlin station.

THE HELIOGRAPH.—Devices for signaling, very similar to the heliograph or "sun writer," have been in use for ages. As far back as the Persian invasion of Greece, polished metal surfaces were used to flash the rays of the sun and give warnings of one kind or another. The signaling in this and other cases was, however, imperfect, and could not be carried on over a space of more than 18 miles. But the instrument now in use, the Mance heliograph, is a great improvement, for it not only concentrates the sun's rays but it flashes them with the utmost precision to any required spot, irrespective of the relative location of the sun. It is also provided with a finger key, so that flashes may be made of long or short duration, thus permitting the employment of the Morse telegraphic alphabet. Under favorable conditions intercourse has been carried on through the medium of two of these instruments over a distance of nearly 100 miles, and at several points occupied by the English army in Afghanistan, regular communication is maintained at distances of not less than 50 miles by heliographic signals. The instrument weighs only seven pounds and can be carried and worked by one man. It is, of course, useless in cloudy weather. It has already been proposed to establish a systematic telegraphic communication between various islands in the West Indies by this process, and before long it will be adopted as a means of signaling between vessels when at sea.

Journal of Tel July 1/79

[From *The Journal of the Franklin Institute.*]

Mance's Heliograph.

DEVICES for signaling, in many respects similar to the heliograph, have been in use for a very long period of time. We have a record of the employment of polished metal surfaces to flash the rays of the sun, and thus give warnings of one kind or another, which dates back as far as the Persian invasion of Greece. Immediately after the battle of Marathon, the defeated Persians were signaled by some one on the mountains near Athens, by means of reflected rays of the sun upon the polished surface of a shield, that the city would be put into their possession if they came there immediately with their fleet. Fortunately, in this instance, the signaling was seen by both sides, and the ready interpretation of it by the Greeks, and their speedy return to Athens, saved the city from falling into the hands of the enemy. In this case, the signaling must have been carried on over a space of about eighteen miles, and, with the rude appliances used from that time down to a very recent period, this was about as far as the system could be depended upon to work. But the instrument now in use, the Mance heliograph, is a great improvement on the old methods, for not only does it concentrate the sun's rays, but it flashes them with the utmost precision to any required spot, irrespective of the relative location of the sun. It is, moreover, provided with a finger-key, so that flashes may be made of long or short duration, in this way permitting the employment of the Morse telegraphic alphabet. Under favorable conditions, intercourse has been carried on through the medium of two of these instruments over an intermediate distance of nearly one hundred miles; and at several points occupied by the English army in Afghanistan, regular communication is maintained at distances of not less than fifty miles by heliographic signals. The instrument is admirably adapted for war service, as it weighs only about seven pounds, and can, without difficulty, be carried and worked by one man. Of course, in cloudy weather it is wholly useless, and for this reason can never entirely take the place of flags or field telegraphs; yet there are so many days in a year in which it can be used that it will be strange if it is not made use of in various parts of the world, for commercial as well as military purposes. It has already been proposed to establish a systematic telegraphic communication between various islands in the West Indies by the heliographic process; and we venture to think that before long it will be adopted as a means of signalling between vessels when at sea.

Journ of Tel Aug 1 1879

Dr. Hooke's Telegraph.

IN 1684, Dr. Hooke proposed a kind of mechanical telegraph which, however, was not carried into operation. He prepared as many different shaped figures in wood, as, for example, squares, triangles, circles, etc., as there are letters in the alphabet. He exhibited them successively in the required order, from behind a screen, and proposed that torches or other lights, combined in different arrangements, should supply their place at night. Twenty years later Amontons, of Paris, exhibited some experiments before the Royal family of France and the members of the Academy of Science, showing the practicability of the system.

Mirror Telegraphy.

Journ of Tel Aug 1 1879

INTELLIGENCE from the Cape says that communication has been established between Ekowe and Fort Tenedos by mirrors. It may be of interest to state that some four years ago Lieutenant Parrott, of the Volunteer Engineer Corps of New South Wales, conducted a series of very successful experiments in mirror telegraphy. The discs used were about six inches in diameter, of polished metal, covered with glass. At first the distance separating the two mirrors was from six to ten miles, but eventually the system was tested from the Kurrajong Mountain, about 1,500 feet above the level of the sea, to the lighthouse at the entrance to Port Jackson, 400 feet above sea level, a distance direct of nearly forty miles. Communication was kept up throughout the day with perfect success by rapid and prolonged flashes, representing letters, words, and phrases, or, rather, questions and answers. The flashes are, of course, produced by slightly moving the mirrors. Successful tests were also effected by moonlight for a distance of four or five miles, and on dark, clear nights this system of telegraphy may be carried on by means of lamps with powerful reflectors, the light therefrom being thrown on to the signaling disc. The advantage of this mode of communication during war is apparent to every one.

SOCIETY OF TELEGRAPH ENGINEERS.

INAUGURAL ADDRESS.

Engineering

By WILLIAM HENRY PREECE, President.

In surveying the wide sea upon which the numerous and varied practical applications of electricity are launched for the subject of this evening's address, I have been puzzled to steer a course that shall avoid the dazzling shoals of theory on the one hand, and the dry hard rocks of practice on the other. Hypothesis is a veritable Scylla that captivates the imagination, and often sends the visionary to destruction, while practice alone is a hard-hearted Charybdis that lures the matter-of-fact practical man to folly and expense. Practice must be tempered with theory to utilise advantageously the great forces of nature, and theory itself must be based on practice, or on facts, to be comprehensive and acceptable. Hence success is the offspring of the marriage of practice and theory, and, therefore, as the two are so intimately connected, I have determined to steer a middle course to-night to survey the progress of each in our profession, and to show their mutual relationship.

What is theory? It is an explanation of the hidden cause of certain effects that are evident to the senses. It is an effort of the imagination to account for operations that are in themselves invisible and insensible, but which result in facts that are observable and known. Thus the movements of all those bright bodies by which

"the floor of heaven
Is thick inlaid with patines of bright gold,"

are explained by the theory of gravity. Their appearance, vagaries, and beauties are accounted for by the undulatory theory of light. The warmth that the monarch of them all shed upon this earth countless ages ago, and that is now restored to us in our household fires, is explicable on the molecular theory of heat. The constitution of matter and its various states of solid, liquid, and gas, are completely explained by the atomic theory of Democritus and Dalton, and the modern kinetic theory of gases.

It is impossible for a practical man who has devoted more than a quarter of a century to the application of electricity to useful purposes, to avoid devoting much contemplation to the nature of the agent which he has to make use of. The imagination cannot be checked. The mind will dream and theorise. The untutored savage fancies he hears in the roar of the thunder the anger of the Great Spirit, and the tutored Greek saw in the daily course of the sun the chariot wheels of his god Helios, and in the grey dawn of the morning the advent of the soft and gentle Aurora. The Saxon churl saw in the lambent flame of the phosphuretted hydrogen of his marshes the gambollings of Jack-o'-lantern, or the treacherous ways of Will-o'-the-wisp. Is there a member of this Society who has not striven to peer into the region of the unknown, who has not speculated on the power he uses, or who has not formed some conception in his mind of the nature of electricity? Yet it is remarkable that the answer to the question, What is electricity? cannot even now be given with authority. Faraday, our great apostle, whose researches should be every electrician's bible, declined to venture an answer, nor did he ever directly formulate his ideas on the subject, though his publications indicate pretty clearly and with no uncertain sound what they were. Clerk-Maxwell, while he overthrew all existing theories, failed to supply their place before he was so untimely removed from us. Sir William Thomson, in his published papers, always carefully eschews the consideration of any physical theory of electricity. The French electricians simply use the one-fluid theory as a convenience of language, while the Germans, as a rule, employ the two-fluid theory merely for mathematical purposes. Hence there is no recognised theory of electricity. Some maintain, with Du Fay or with Franklin, that it is a form of matter—a substance; others, following Faraday and Grove, consider it a form of force—a motion—like heat and light. It must be either one or the other. There is no other category in which to class it. If it is not a form of matter it must be a form of force. The question I purpose to discuss is, therefore, Is electricity a form of matter, or is it a form of force?

In discussing such a vexed question it is necessary to be very precise in language to avoid any misconception of my meaning, therefore I will define both matter and force in the sense in which I use those terms. Matter is that which can be perceived by the senses, or can be acted upon by force. It is characterised by weight, inertia, and elasticity. Force is that which produces, or tends to produce, the motion of matter. It may be pressure, tension, attraction, repulsion, or any thing capable of causing alteration in the natural state of rest or of existing motion of matter.

Matter consists of sixty-four known elements which have not yet been decomposed by any known means. There may be other elements that have not yet been discovered by chemists, but they must exist in some known compound. Matter is found in either the solid, liquid, gaseous, or ultra-gaseous state, and it occupies space. It consists of molecules and atoms. The atom is the smallest indivisible part of an element, and a group of atoms of the same or of different elements forms the molecule, which has a definite magnitude and is unalterable in form for each substance. The mass of a substance is the aggregate of the molecules of which it is composed. There is no generation or destruction of atoms. The indestructibility of matter is a fixed law in nature. The size of the molecule is approximately known. Sir William Thomson says: "If we conceive a sphere of water as large as a pea to be magnified to the size of the earth, each molecule being magnified to the same extent, the magnified structure would be more coarse-grained than a heap of small lead shot, but less coarse-grained than a heap of cricket balls." Fifty million molecules ranged in a single file would occupy an inch. They are highly elastic, and unless interfered with would move with constant velocity in straight lines. When they can move about freely without interfering with each other's proceedings, we have the ultra-gaseous state of Crookes, a state found only in very high vacua and under certain adventitious circumstances. When they collide and impinge on each other according to the law of the impact of elastic bodies, interfering with each other's path, we have gases as we know them; when their mean free path is so reduced as to bring them within the sphere of mutual attraction, without too narrowly restricting their play, we have liquids; when the attraction becomes cohesion and the motion of the molecule is confined to its own sphere, we have solids. The number of molecules in a given volume of gas is known, and their velocity calculated. In hydrogen the velocity at 0 deg. Cent. is 6097 ft. per second, the number being 10[illegible] per cubic inch. The mean free path of a molecule in air at ordinary pressures is the ten thousandth part of a millimetre. Besides their constant motion in straight lines the molecules may be set in vibration, rotation, or any other kind of relative motion whatever.

This is the atomic theory of matter born in the brain of Democritus "the laughing philosopher" 2300 years ago; preached by Epicurus in Athens, and taught by Lucretius in Rome before the Christian era; lying dormant for eighteen centuries, until it was formulated by Dalton in the last century, and removed from the region of pure speculation by Joule, Clausius, Clerk-Maxwell, and Crookes during our days.

The definition of force shows us that whatever changes or tends to change the motion of matter (or of the molecules of which it is composed), by altering either its direction or its magnitude, is a form of force. Thus gravity is a form of force, for it attracts all matter to the centre of the earth, and it is measured by the rate per second at which a body acquires a velocity in this direction when falling freely at a given spot. Heat is a form of force, for it throws the molecules of matter into violent vibration, or it increases the velocity of their motion in straight lines, which thus becomes the measure of its heat or its temperature. Light is a form of force, for it is produced by the modulation of the molecules of matter, and it is transmitted by the undulations of that medium called ether, which fills all space.

No man has seen or can see a molecule, nor have we any objective idea of what force really is. When we attempt to reach beyond these definitions, we tread upon the threshold of the holy of holies, on whose confines only are we permitted to dwell, and into which we are not yet allowed to enter. "Hitherto shalt thou come but no further, and here shall thy proud waves be stayed." Let us, therefore, be content with precise definitions and clear mental conceptions, speculative though they be, of matter inert and of matter in motion. The *ultima thule* of the scientific man is theory, and at any time his most cherished notions may be

"Melted into air, into thin air."

The scientific man, while rather too fond of decrying the exercise of faith in others, is himself the humblest slave of the imagination. A physical theory may be complete. The various facts and laws which it embraces may be related mathematically with one another, yet one single incompatible phenomenon may dissolve it,

"And, like this insubstantial pageant faded,
Leave not a rack behind."

Hence, while apparently dogmatic in my description of the present theory of matter and force, I wish it distinctly to be understood that it rests, and must continue to rest, on the imaginative power of the mind.

Nevertheless, subjective speculation may become objective reality. Who is there that doubts the existence of the ether filling all space, transmitting those exquisite and delicate vibrations which impart to us the sensation of light and heat from stars and nebulæ countless millions of miles away? And with regard to the atomic structure of matter, though but a speculation as yet, it is so complete, so apt, and so thorough, that for my part I have not the slightest doubt of its reality, and therefore I submit it with apparent dogmatism.

When we take a given free mass and impress upon it a given force, we throw that mass into motion; for instance, when we fire a loaded cannon, we have imparted to the ball "energy" and in virtue of the motion of the ball, this energy is called "kinetic." Again, if we lift the ball to a certain height above the earth's surface—say to the top of a tower—and let it remain there, we have again imparted to it "energy," but this time it is called "potential," for it is dormant or resting. In each case the energy possessed by the ball is the exact equivalent of the work done upon it, that is, of the force impressed and the distance through which it has acted. The motion of the ball is readily transferred to the motion of the individual molecules of the ball. When, in the first case adduced the ball strikes the side of a ship or a target, its kinetic energy is thus converted into light and heat, which is molecular motion; or, in the second case, when it is allowed to fall, its potential energy is converted into kinetic energy, which again, on coming in contact with the ground, is converted into molecular motion or heat. Energy is always either potential or kinetic, and one of the most remarkable generalisations of modern days is the grand principle of the conservation of energy, which implies that the total energy of the universe is a quantity which can neither be increased nor diminished, though it may be transformed into any of the forms of which energy is susceptible. Energy is therefore as indestructible as matter. All the recent advances in the science of heat have been due to the discovery of this principle, and its application to electricity has gone far to remove that science from the hypothetical state to which it has existed so long.

My purpose is to contend that electricity is not a form of matter but a form of force, and that all its effects are evident to us in one or other of the several forms of energy characterised by the motions of molecules or of mass.

It is interesting to trace the historical growth of theories. The uncultivated human intellect cannot soar above its own limited sphere of childish observation. Whatever is mysterious and incomprehensible in nature is attributed to that which is equally mysterious and incomprehensible. Life has ever been of this character, and heat, magnetism, electricity, and many other unaccountable physical phenomena, have each in their turn been supposed to be cases of life. Even now there are those who would attribute exceptional and peculiar phenomena to spiritual agencies.

Heat was thought by the Greeks to be an animal that ... was then for many centuries thought to be a fluid which ... ering into bodies, like mercury, made them swell, and this idea existed until this generation, when Rumford showed it to be a kind of motion, and Joule made it a quantitative form of energy.

Thales, of Miletus, thought that the magnet was endowed with a sort of immaterial spirit, and to possess a species of animation. The Greeks knew also that rubbed amber attracted bits of straw, and supposed it to be endowed with life. Even Boyle, as late as 1675, imagined it to emit a sort of glutinous effluvium which laid hold of small bodies and pulled them towards the excited body. Du Fay in 1733 conceived the double fluid theory, and Franklin in 1747 invented the single fluid theory. Cavendish in 1771 supplied some of the deficiencies of Franklin's theory, but it was Faraday who first exploded the fluid notion and originated the molecular theory of electricity, while Grove boldly classed electricity with light and heat as correlated forces and mere modes of motion.

Light was thought by the Platonists to be the consequence of something emitted from the eye meeting with certain emanations from the surface of things, but no theory of light properly so called was attempted until Newton produced his celebrated corpuscular theory in 1670, which has lasted until the present day. Even as late as 1816 Faraday himself said:—"The conclusion that is now generally received appears to be, that light consists of minute atoms of matter of an octahedral form, possessing polarity, and varying in size or in velocity." Although Huyghens in Newton's own time conceived the undulatory theory, the superior authority of the great English philosopher overshadowed the lesser light, and it was not until Young and Fresnel, at the commencement of this century took the matter up, that the present theory of light took firm root.

Thus we see that all these sciences have passed through the same stages of mystery and fancy, and it is only within the present generation that they have emerged from the mythical to the natural, from mere hypothesis to true theory. Hypothesis is an imaginary explanation of the cause of certain phenomena which remains to be shown probable or to be proved true. Theory is this supposition when it has been shown to be highly probable and all known facts are in agreement with its truth.

(*To be continued.*)

ELECTRICITY, TELEGRAPHY

from ... 1880

MR. GRAHAM BELL.—The committee appointed by the French Minister of Public Instruction has awarded the Prix de Volta—50,000 fr.—to Graham Bell.—*Nature*.

THE FRENCH-AMERICAN CABLE.—The new French cable for America has been placed at the disposal of the public for correspondence. It goes direct from Brest to St. Pierre, and from St. Pierre to Massachusetts, where it is connected with the American Telegraph Union. A new cable will be laid from Brest to Penzance by the *Faraday* steamer, in the beginning of February, and afterwards from Penzance to St. Pierre. The second cable will be used for English telegrams.

THE PACIFIC CABLES.—It is now announced that the duplicate Australian cable has been completed, and is open for traffic. The new cable takes a somewhat different route to the original. The old cable from Singapore landed at Batavia, and the messages were sent over the Dutch Government lines to Banjoewangie, at the furthest extremity of Java, where the Australian section of the cable commences. By the new arrangement the Singapore section is taken direct to Banjoewangie, thereby avoiding the Java land lines, which will effect a great saving of time and tend to greater accuracy, as the messages will pass entirely through English hands.

NEW ELECTRIC CANDLE.—A French inventor, M. Perruche, has presented a new description of electric candle to the Paris Academy of Science. The candle consists of three carbons, two being cylindrical and 0·003 metre in diameter, and applied to each other; the third of square section, 0·005 metre inside, and placed in the angle formed by the first two. The cylinders are in pivoted brass holders between brass plates brought together by a spring. The holder of the square carbon is also capable of oscillation, and the carbon is held by a spring in contact with the other while no circuit passes, but, when the current begins, takes its separate position. It is regulated by an iron lever and electro-magnet in circuit.—*Electrician*.

THE POST OFFICE AND THE TELEPHONE.—With reference to the actions which were recently entered against the Telephone Company for alleged infringements of the Postal Telegraph's monopoly, the *Western Morning News* is enabled to state that an arrangement has been entered into between the Post Office and Bell's Telephone Company by which not only proceedings against the company will be abandoned, but the Postmaster-General undertakes to give every facility for the extension of telephone communications. The Telephone Company will pay a royalty to the Post Office, and may use the post offices and staffs under certain conditions for their work. Thus telephone wires may be run from a post-office to the town offices or country residences of gentlemen, and telegrams arriving at post-offices for them may immediately be communicated by telephone, thus saving time. To country gentlemen whose residences are distant from the nearest telegraph offices this accommodation will be invaluable. Telephone extension is progressing rapidly. One firm, whose offices are in London and Manchester, are laying a wire for telephones between their two establishments.

AN ELECTRIC LOG.—The well-known Massey's log is far from being a perfect instrument; one disadvantage is, that its counter being under water, the velocity at a given moment cannot be determined, and if there is a stoppage, one's ignorance of the point at which it occurred may render the indications rather useless. It has often been proposed to use electricity to transmit log-indications, as this would obviate the inconveniences just noted. An electric log, devised by M. Fleuriais, has been fully tested, with satisfactory results, on board the French frigate *La Magicienne*, in a recent long cruise. From a description of it in *La Nature* we gather that it is partly based on the principle of Robinson's cup-anemometer. A four-armed cross-piece, with cups at the ends of the arms all directed similarly in relation to the arms, is supported on a vertical axis so as to rotate in being pulled through the water, and proportionally to the rate at which this is done. The "mill" is of bronze; but to diminish friction the axis is supported in small blocks of guaiacum, which are at the ends of the arms of a bronze fork, presenting little resistance to the water. This fork is attached, through a short chain, to the log-rope, one strand of which is removed to make a place for the electric cable (a Menier military cable, with seven wires). The wire of the cable passes from the negative pole of a battery on board ship to the log, while the "earth wire" passes from the positive pole into an electric bell (without trembler).

ENGINEERING.

FRIDAY, JANUARY 30, 1880.

TELEGRAPHIC ENGINEERING IN 1879.

In dealing with the general advance of telegraphic engineering during 1879, there are two divisions of the subject under which it may be considered, viz., first, the extension of works, and secondly, the improvements in the apparatus and means employed. As regards the postal telegraph system which forms the greater part of all telegraph lines in England—the rest being the wires used for railway signalling—there has been very little extension of the lines, yet 94 new stations have been opened. There has, however, been a constant advance in the perfection of the apparatus; Wheatstone's automatic apparatus has been duplexed on numerous circuits, and translating relays have been placed at the ends of all submarine cables in circuit on automatic circuits, which has increased the speed 100 per cent. Quadruplex has been extended also to several circuits. The iron wire used for the overground lines has now to be of a specified conductivity, of a certain tensile strength, and to stand a specified torsion, and although the German wire drawers can supply wire for the outer covering of submarine cables delivered on the banks of the Thames cheaper than our inland manufacturers, they cannot supply the wire of the quality required by the Post Office as cheaply as English makers. In the underground wires the Post Office now adopt, wire with only a single covering of gutta-percha, and a new mode of making the joints in the gutta-percha covering by an apparatus invented by Mr. Truman, has been tried with success and is likely to be adopted. A new four-conductor cable has been laid by the Post Office between Port Patrick and Donaghadee to replace the old one; defects have been repaired in the cable between the Welsh coast and Wexford, and 45 miles of new cable are being manufactured by the India-Rubber, Gutta-Percha, and Telegraph Works Company for the renewal of a part of this line. The Shetland Isles and Orkney cables have been repaired. A system devised by the Post Office engineers and electricians of indicating the rise and fall of water in water reservoirs at the engineer's office situated away from the reservoir, has been adopted at the Nottingham and Southport Water Works, and it is to be fitted at other similar places. In a general way the year as regards the Post Office telegraphs has been one of steady progress without any important extensions.

The first establishment of telephone exchanges in England marks this year's history of telegraphic progress. The Telephone Company established about two years ago for the supply of Bell's telephone for private circuits, has, since August of this year, established telephone exchanges in London, Liverpool, Manchester, Glasgow, Dundee, Birmingham, Bristol, Leeds, Sheffield, Bradford, Halifax, &c. The London subscribers amount to 250. The central station is at 36, Coleman-street, and each subscriber can, by calling the central station and demanding to be switched through to any particular member, be thus placed in speaking communication with such subscriber. The lines are mostly carried over houses, but some wires to Westminster are carried along the Metropolitan District Railway. The instrument used is Blake's transmitter, which is a microphone and induction coil with battery in primary circuit, and secondary connected to line, and a Bell's telephone for receiver. Besides the circuits for the telephone exchanges, the company have put up some fifty circuits in London and elsewhere for private firms, including the General Post Office, several dock and railway companies' offices, &c.

The Edison Telephone Company, of London, central office 11, Queen Victoria-street, was established this year early in September for a similar purpose, Edison's telephone being employed. This instrument, which we have fully described, consists of the Edison carbon receiver and the Edison chalk cylinder transmitter; its articulation is loud and clear, but it requires to have the chalk cylinder revolved by hand. Besides the central station there are stations at 34, Eastcheap, 77, Cornhill, and 6, Lombard street, and arrangements are being made for stations at Westminster, Temple, and Pall Mall. The wires are mostly overhead, but some are to be carried to Westminster in the Metropolitan Board of Work subways. The company has already forty subscribers to the Victoria-street centre, sixteen to Eastcheap, and ten to Lombard-street. One of the circuits from Victoria-street extends to Beulah Hill, Norwood, and amongst the various private circuits established by this company is one between Brighton and Littlehampton, 22 miles in length.

As regards submarine telegraph engineering, the extensions have been considerable. We may first mention the submarine line from Aden to Durban laid for the Eastern and South African Telegraph Company. This cable was constructed and laid by the Telegraph Construction Company, and consists of four sections, namely:

	Nautical miles.
Natal to Delagoa ...	
Delagoa to Mozambique	315
Mozambique to Zanzibar	969
Zanzibar to Aden	625
	1902
	3811

It was completed on Christmas Day; the core consists for the three first sections of a conductor of 107 lb. of copper and 140 lb. of gutta-percha to the nautical mile, and the long section, of 250 lb. of copper and 250 lb. of gutta-percha to the nautical mile. Messrs. London and Lucas were the engineers, and Mr. Laws the electrician on the part of the Construction Company at the laying of the cable, and Mr. Forde and Mr. Hockin, of the firm of Clark, Forde, Hockin, and Taylor, were the engineers on the part of the Eastern and South African Company.

The duplication of the Eastern Extension Company's system from Penang to Port Darwin in Australia, is also a work of great magnitude which has been commenced this year and three parts completed. This when completed will be as follows:

	Nautical miles.
Penang to Malacca ...	
Malacca to Singapore	275
Singapore to Banjoewangie (Java) ...	116
Banjoewangie to Port Darwin ...	620
	1180
	2191

The core of this cable is composed of 107 lb. of copper and 140 lb. of gutta-percha. Of these the three first sections are completed, and the rest of the cable is about to be laid by the s.s. Seine. The whole of this work is contracted for by the Telegraph Construction Company, Mr. Riddle being the engineer in charge on their part, and Mr. Herbert Taylor on the part of Messrs. Clark, Forde, Hockin, and Taylor, engineers for the Eastern Extension Telegraph Company.

In both these works two new features have been introduced which should be marked as dating from the year 1879. The first is a means of protecting the gutta-percha insulating medium from the borings of the teredo, and other marine insects which have been found to attack the core in shallow seas, and more particularly in the cable between Singapore and Batavia, very many faults having been thus caused. The protection consists of a thin tape of brass laid round the core, which has first cotton tape wound round it to form a bed for the brass tape, and prevent the delicate gutta-percha from injury by the edges of the brass tape. Over the brass tape another layer of cotton tape is placed to keep the former from buckling open. This covering is again served in the usual way with jute forming the bed for the outer wires. In both the duplicate Australian and Cape cables, wherever the cable lies in shallow water, the core is thus protected. The second novelty is in the deep-sea portion only; it consists in placing cotton tape saturated in preservative compound, round each of the homogeneous iron wires separately in order to protect them further from rust, the whole cable being further surrounded, as is now usual, with two layers of broad tape wound in opposite directions and covered with preservative compound. The covering of the wires separately with tape is, it should be remarked, only new as regards its being adopted for deep-sea cables, as it was adopted in shallow water on the present Post Office cable between Holyhead and Dublin cable laid in 1871.

A cable for the German-Norwegian Telegraph Company was laid by the Telegraph Construction Company between Arendal, in Norway, and Hoyer, in Schleswig. The cable is 252 nautical miles in length, and has three conductors each of 100 lb. of copper and 125 lb. of gutta-percha per nautical mile, covered with twelve No. 5 iron wires galvanised, and protected with two layers of tape and compound. The company also made 120 miles of cable for the New Zealand Government, which was shipped in the s.s. Kangaroo with some of the cable for the Aden-Zanzibar section of the Cape cable, and will be laid by that ship. Mr. W. H. Preece was consulting and Mr. F. C. Webb inspecting engineer, for this cable, which was ordered by telegraph from New Zealand through Sir Julius Vogel, the Agent-General.

The whole of these works, comprising 6704 miles of cable, mark the most busy year even of the Telegraph Construction Company's existence. The company have also this year added to their fleet the magnificent steamer Scotia, formerly the well-known Cunard paddle steamer, and now converted into a twin screw. She is 4666 gross, and 2031 net tonnage, she is 379 ft. long, with engines indicating 2500 horse power, and she has carried a dead weight of 4300 tons. She has water-ballast tanks for 780 tons, and carries three cable tanks below her main deck. The vessel is fitted with two picking-up gears complete, and these are placed on the main deck, the tops of the drums protruding through hatches in her spar deck. This, both as regards the machines being on the main deck, and being in duplicate, is a novelty dating from 1879. She has also duplicate drums to her paying-out gear, and has also steam-steering gear. The vessel has been fitted under the supervision of Mr. Clifford and Captain Halpin, and is decidedly one of the finest cable ships afloat. She went to Singapore, laid her full cargo of cable, and came back in 3 months and 17 days, having steamed 17,850 miles with an average daily consumption of 38 tons. The other

It would have taxed the imagination of the [illegible] few years ago to conceive how a new ocean cable [illegible] comprising thirty-[illegible] of wire, all centring in New York, could go into operation, as they did yesterday morning, with so little formality, noise and fuss. There were no congratulatory messages, no exploding of guns or after-dinner speeches, no splurging in the newspapers. There was even no bluster about a reduction of rates. The new French cable company, the Compagnie Française du Télégraphe de Paris à New York, began its business existence quietly, with an interchange of private commercial telegrams and did a light day's business. It has not put down rates, although the old rival Anglo-American Cable Company announces that its tariff after February 1 will be reduced from seventy-five cents to twelve and a half cents a word. The lines of the new company extend from Brest, France, to St. Pierre, Cape Breton, Newfoundland and thence to Nauset Light, Cape Cod. From St. Pierre there is a connection in Louisburg, Canada, and from Cape Cod to this city. A cable from Brest is about to be laid by this company to Land's End, England, and from that point another ocean wire will be stretched to St. Pierre, the American landing point. But the quiet opening of the American Union Company yesterday is a yet more notable event. That company, having overcome all obstructions in the courts, goes to work with thirty-five thousand miles of wire, connecting all leading American business centres with the new French cable and with each other, skimming the cream of the telegraph business of this country, and working on a capital that is nominal in comparison with that of its older competitor. Curiously enough this company does not yet talk about reducing rates. It certainly ought to do so, however. It is to be hoped that the American business community at last has a telegraph system that will compete with the old monopoly instead of selling out to it.

EFFECT OF POLARIZATION UPON FRICTION.—Herr Koch has made an interesting experiment regarding the effect of polarization upon friction, the result appearing to have a bearing on the action of the Edison friction telephone. When a plate of platinum or palladium is polarized by means of an electric current, the friction of these metals against a plate of moistened glass increases immediately. To measure the friction, Herr Koch uses the metal in the form of a hemispherical button, resting on the bottom of a glass cup filled with pure or acidulated water. The button serves as a pivot to a magnetic needle, which oscillates under the action of the earth; the decrease of the oscillations measures the friction of the pivot. Polarization is produced by the current of the Daniel element, one pole of which communicates with the metallic button, while the other terminates with a platinum wire entering the water of the cup. The polarization by hydrogen produces no effect, but polarization with the pole oxygenated is found very efficacious. The friction was increased, through this polarization, in the ratio of 2 to 3, and sometimes in that of 2 to 4. This increase of friction appears immediately after the circuit is closed, and disappears immediately when the current is reversed; but it disappears slowly, like the polarization itself, when the circuit is merely opened. Palladium behaves like platinum. Gold gave no effect.

ON Wednesday, September 8, lightning fell on the Sorbonne at about half-past two o'clock. A globe of fire was observed by persons present on the spot. Some of them say it was seen coming from the point of the north-western conductor, which was struck, as well as the south-western, with a great noise. The Sorbonne had, until recently, no lightning conductor, and never, as far as is known, has any thunderbolt struck the venerable abode of the French University. But within the last few months six stems have been erected and connected by an iron bar, making a circuit which goes all over the roof of the immense building. Unfortunately the pit where the earth conductor has been placed is situated at a great distance from the main building, in a courtyard adjoining the laboratory of M. Jamin, and the conductor which connects the roof with this is a square iron box of less than 15 mm. on each side, so that there is not sufficient conductibility in it to establish an efficient connection with the earth. This accident proves the sagacity of M. Karsten, the Schleswig Holstein physicist, who published a table giving a formula for regulating the dimensions of the connecting-rods with their lengths, as is taught by Ohm's laws. It shows also how little the knowledge of lightning-conductors is spread in France, in spite of the several official commissions which have been established by the Government. Nature Sept 18 1880

SOME RECENT ADVANCES IN TELEGRAPHY.—VII.*

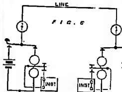
YOU were shown in the first lecture that by passing a current through an electro-magnet attraction and repulsion are produced. This attraction and repulsion gives us mechanical power, which we turn into account, and make it the means of indicating by long or short beats the elements of letters that are sent by the current. Here is a Morse embosser. To the armature of the electro-magnet is attached a lever, at the end of which is a style. Each time the armature is attracted the bar is moved, causing the style to press upon paper ribbon, which is mechanically drawn over a ground wheel, and if a succession of short currents be sent through the electro-magnet, as many dots are embossed upon the paper ribbon; or, if currents causing the armature to be held down for a sufficient time to represent the "dash" element of a letter, as many dashes appear on the paper. But this embossing is difficult to read unless you catch the shade falling upon the dots and dashes, which operation severely taxes the eyes. In 1851, Thomas John, an Austrian engineer, devised a plan by which these dots and dashes could be made in ink; and before you is one of the earliest ink-writing instruments employed, made by the eminent firm of Siemens and Halske. There is exactly the same motion as in the embosser, but instead of the style at the end of the lever, a disc is fixed, which rises and comes in contact with the paper in the reverse direction to which it is rotated. The disc dips into a small well containing ink, and as it revolves continually in the reverse direction to that of the paper, it presents ink on its circumference to the paper and so records dots or dashes, whichever may be sent. With a simple ink-writing instrument such as this it is difficult to get currents of sufficient strength to attract the armature at great distances with force enough to make a mark on the paper. In that case what are called relays are introduced. Let us suppose a line of telegraph as shown in Fig. 6.

You have a battery, with a key, by the simple depression of which a current is sent to line. You have also a galvanometer, which shows whether the current flows or not, and at the end of your line wire you have a "relay" which receives the current, however weak, and immediately brings into force a more powerful current, which passes through the electro-magnet of the instrument, and records the signals received. There has, perhaps, been more ingenuity exercised in the construction of these relays than of any pattern of apparatus used. Here is one of the first relays ever used. It was introduced by Wheatstone to send an alarm, and was produced by the decomposition of water. The gases accumulated by the decomposition of the water drove up, by pressure, a column of mercury, which made contact, and so sent an alarm. Another form of relay was by the mercury contacts made by a fork fixed at the end of a needle as you see here. One of the earliest forms of relay introduced into America, and that which is almost universally used over there now, is the Morse. It has certain advantages over other kinds, but being non-polarised, is abandoned in this country, and superseded to a great extent, by that known as Siemens' relay. Here is another relay known as Stroh's, which is extremely delicate and moves with the slightest current, but the most recent one is that known as the Post-office standard relay. All these instruments will be better understood by a little careful inspection; it is quite impossible for me, in the time allotted, to explain their construction. They all perform the same function, viz., to bring into play stronger and more constant currents.

The instrument I have explained to you records dots and dashes on the paper, but you will have noticed that in making these marks a certain sound or beat occurs. Sometimes we read by this sound, and the current performs the dual function of attracting consciousness, either through the eye, by reading the dots and dashes on the paper, or through the ear, by the sounds. We have here, in order to show the actual working of the telegraph, an instrument fixed on a wire, which communicates with the Central Telegraph Station in St. Martin's-le-Grand. It is one of the simplest kind of instrument, a sounder. To show you how these sounds can be translated into the Morse alphabet, I have brought a little instrument (kindly made for me by Mr. Theiler), which emits a fairly loud tone of given pitch.

This little sound-giver is very similar to one brought out some years ago by Mr. Brittain, and was called (after him) "Brittain's Busy Bee."

But the sounder instrument, instead of emitting a musical tone, simply gives a thud, though I would ask you to notice that the sound produced by the attraction of the armature is quite distinct from that made on its recoil. This kind of instrument is used to a very large extent (almost universally) in America; it is a specimen, in fact, of the "pony" sounder used in America, which I brought over on my recent visit. We have rather altered it, and, I hope, improved upon it. We will now call up the attention of the Central Station, and you will have a practical illustration of the manner in which telegraphic business is carried on. To call up an office certain signals, which represent the code of that office, are sent. Every telegraph office throughout the kingdom has its code; Liverpool, for instance, is L V; Manchester, M R; Birmingham, B M, and so on. The code for London is T S, which letters (representing the telegraphic centre of the world) are the initials of Telegraph-street, where the Central Office was formerly situated.



SINGLE CURRENT CIRCUIT, WITH RELAY

That is the actual process adopted for the transmission of news and ordinary messages. You will readily understand upon what trifling differences in sign or tone words depend. The insertion of a dot here, or the omission of a dash there, is sufficient to cause an error. But in spite of this it is very surprising and pleasant to find that out of the 100,000,000 messages repeated every year so few errors are made.

A dot will convert the word save to rave; pound is easily transposed into found, and the words dead and bad are made up of precisely the same number of dots and dashes, as

D E A D B A D

the only difference being the insertion of a space; and a very sad message was sent not very long ago announcing that a favourite daughter was "dead" instead of "bad"—the signals for DE having exactly the same element as B, as shown above. After hearing this you will not be surprised that when a party of young ladies was announced as having "arrived all right," the message was delivered as "arrived all tight;" and that also when a husband went to Brighton to secure apartments, and arranged with his wife that if he found apartments he would telegraph for her to come, but if unsuccessful would return home; he telegraphed "home to-night," but she received the message "come to-night," and the result was that they crossed on the road. Again, a friend of mine was in Manchester, and his only child was at home unwell, he suspected, with the measles; his wife telegraphed "Rash all gone," but he received a message "cash all gone." I could repeat these errors to any extent, many ludicrous, many sad, but all simply dependent upon a very trifling change made in this rather uncertain alphabet. Still, as I said before, when we think of the enormous number of messages transmitted every year, we can only be surprised at the care and skill which prevents a greater proportion of errors.

I want particularly to call your attention to the difference between the ink-recorder and sounder. The latter is the instrument now coming into use with tremendous strides. It has had to force its way a good deal against prejudice and ignorance, but it is steadily and surely making its way into this country. Its extreme simplicity is most striking. In the apparatus upon which you have just heard the news received, we have everything sufficient to fully equip a telegraph station. We have a table upon which is placed your key, galvanometer and sounder, with battery underneath. The galvanometer is simply for the purpose of indicating when a current is being received, should the sounder fail. The advantage of this instrument is its economy. The difference between the cost of a sounder and ink-recorder is very great. Again, the clerk who reads by the sounder, and writes down the message, uses each sense separately, but with the recorder he has to refer to the slip with his eye each time he has written out as much as he noticed by the previous glance, and this constant referring means liability to error. With the sounder the clerk's ear drinks in the sound, and it is the same to him exactly as if the sounder were simply speaking to him. The sounder ensures wonderful accuracy in the [illegible] telegrams; and one of the most marked effects of the introduction of this instrument has been the reduction in the number of errors made, the reason being that the hand follows the ear; if the ear has learned to read accurately by sound, the hand is sure to send accurately by sound, and this is invaluable, because where we have a good sound-reader there we have a good sender, and the result is accuracy. Also, as the clerk has not to glance his eye from one paper to the other, but simply to write on as fast as he can, the rapidity of the working is increased, because he simply writes down as fast as he is sent to, and, in point of fact, the rate at which messages are taken off is simply limited by the rate at which the clerk can write. It instils into the clerks who use this apparatus care and reliance. It has a kind of disciplinary agency about it, and those who are skilful sound-readers invariably turn out to be self-reliant, accurate, and valuable operators. But the principal advantage attaching to this sounder is that it in reality increases the speed of working, and thereby increases the capacity of the wire for the transaction of business. Certain disadvantages are asserted as belonging to sound reading. One objection is the loss of record. That is a very conservative notion. It is supposed that by having a record of each message that you have a check in case of error. But, as I told you, errors on the sounder are not made, and, therefore, no check is needed, and those who support the old instrument on account of its recorder, can only be classed amongst the staunchest conservatives that we possess. Again, it is said that there is some difficulty in reading the sounder, when other noises take place in the room or shop where it is fixed; but I can only say that in the Central and other large offices where sounders are used and many noises prevail, the sounder is in great favour, and has never been objected to on the ground of its being interfered with by extraneous noises. At other times it has been said that listeners can stand outside a telegraph office and hear all that is going on. They may do so in America, but they cannot in England, for in a well-appointed office the sounder, being placed behind the public counter, ought not to be heard (though I am afraid it often is), but, even if it is, I do not think it is likely that people who could read by sound would find it worth their while to hang about to catch unknown and unexpected messages. I do not think there is much value, if any whatever, in these objections. There are about 1,380 of these sounder instruments in use in the Postal Telegraph Department.

There is another kind of sound-reading instrument called the "Bell." This instrument was introduced by Sir C. Bright and his brother, Mr. E. Bright, as far back as 1853. It is after the principle of one of the earliest forms of instrument, which also recorded its alphabet by different sounds, invented in 1837 by Steinheil. The signals are received on plates varying in sound, one representing a dot and the other a dash.

The signals when sent on this instrument at a rapid rate, seem to form, to an unpractised ear, quite a confusion of sounds, but I have no doubt there are many persons in the room who can easily distinguish the signals sent, and convert the apparent conglomeration of sound into ordinary language. There are 277 of these bell instruments in use in the postal telegraph service.

Another form of sound-giving instrument, called the "Neale," from its inventor, has lately been introduced. It follows the principle of the bell, the different sounds being caused by the beating of the single needle upon metal cylinders of different tone. It is made by substituting for the induced coil of the single-needle instrument an "acoustic" coil of the Neale pattern. It possesses all the advantages of the single needle, with the addition of those of sound-reading, and is certainly calculated to simplify some of the difficulties of telegraphy. The instrument has only lately been introduced, and though likely to be largely used in the postal telegraph service, time has not yet permitted of its being generally adopted. There are many other instruments in daily use which I have no time now to refer to.

There are instruments which record the letters of the alphabet in bold type upon paper slip. One of the most valuable, which is very largely used on the Continent, is the Hughes type-printing instrument. It is also used in England by the Submarine Telegraph Company, and the *Times* newspaper has private wires to Paris and Vienna, and all the news that you see every morning from "Our own Correspondent" in these towns is transmitted direct, and printed in clear type on paper slips by this instrument, which can on its receipt be immediately handed over to the compositors to set up. We have only a few of these instruments in the Post-office. It was used very largely at one time, but we found that it was not equal to the speed required. They are, perhaps, a little slower in the transaction of business on the Continent, or have not yet arrived at that tremendous development of business which we experience, and which compels

NOTE ON THE ZODIACAL LIGHT. 1880

Science. BY HENRY CARVILL LEWIS. Oct. 9

The results of a series of observations upon the zodiacal light made by the writer, extending over a period of nearly five years, is here recorded. The special precautions taken, both to train the eye to detect faint lights, and to prevent bias on the part of the observer, were given in detail. The zodiacal light may be divided into three portions—the *zodiacal cone*; the *zodiacal band*; and the *gegenschein*. This division is convenient in observation, saves confusion in description, and may be in part a natural one.

The zodiacal cone.—This, the zodiacal light proper, of most authors, is the well-known cone of light rising along the ecliptic, and best seen in the winter months in the West, immediately after the disappearance of twilight. The time of shortest twilight coincides with its greatest brilliancy. Several observations are given when the writer saw it cast a distinct *shadow* at that time. Its comparative brightness with the Via Lactea at different seasons were given, and its relation to the ecliptic discussed. It was stated that the cone in our latitude is not symmetrical; and that while its axis of greatest brightness lies exactly upon the ecliptic, its axis of symmetry is north of that line. An inner short cone of greater brightness was described. The warm color was shown to be due to atmospheric absorption. No pulsations were ever observed which could not be explained either by atmospheric changes or by changes in the eyesight of the observer. No periodic changes in the zodiacal light were observed; the same series of changes occurring each year with an equal amount of brilliancy. It was shown that while the zodiacal cone is frequently seen by moonlight, the moon appears to have no appreciable influence upon it. The account of the zodiacal cone closes with a description of its *spectrum*, which is always continuous and free from bright lines.

The zodiacal band.—This is an extremely faint zone of light, somewhat wider than the Via Lactea, which, like a strip of gauze, is stretched across the sky along the zodiac from horizon to horizon, and which can be seen at all times. It is a belt which forms a very faint prolongation of the zodiacal cone, and which, like it, is best seen when the ecliptic makes a large angle with the horizon. It is so faint that it can only be seen with difficulty. The best method of observing it is described. It is brightest along an inner line, and fades off more suddenly on its southern than on its northern edge. It has a width of about 12°, and its central line is slightly north of the ecliptic. Observations prove the zodiacal band to be a constant and invariable phenomenon.

The gegenschein.—The gegenschein is a faint patch of light, some 7° in diameter, which nightly appears in that part of the zodiacal band, which is 180° from the sun. Night after night it shifts its place so as to keep opposite to the sun. It is decidedly brighter than the zodiacal band, and occasionally a central nucleus about 2° in diameter, of greater brightness, can be observed. While the brighter portion of the gegenschein is circular, its faint boundaries have sometimes the form of an oval, whose major axis is parallel to the ecliptic. A large number of maps of its position among the stars have been made, which show that while its central point is always 180° in longitude from the sun, it has a latitude of + 2°.

The moon zodiacal light.—An oblique cone of light in the proximity of the moon was described by Rev. G. Jones, but has not been detected by the writer. The light preceding moonrise rises at right angles to the horizon, and seems purely atmospheric. One observer has described comet-like tails on either side of the moon. The writer holds that such appearances are caused by diffraction through floating vapor, since they are never seen on clear nights.

The horizon light.—The phenomenon to which this name is applied, though having no connection with the zodiacal light, is so continually observed with the latter, and at certain seasons is so apt to be confounded with portions of it, that it is necessary to take it into account. The horizon light is a faint band of light with parallel sides, lying all around and parallel to the horizon, and separated from it by an interval of darkness. It is brightest, and terminates most abruptly on its lower edge. This sharp lower edge is 5° above the horizon, while the diffuse upper edge varies in altitude with the state of the atmosphere. The horizon light has a mean width of about 15°. It is purely atmospheric and appears to be caused by reflected starlight. It becomes very bright when the moon is above the horizon. Below the horizon light is a very dark space here called the *absorption band*. This quenches the light of the Via Lactea, the zodiacal cone, and all except the largest stars and planets, which last, while in it, are deeply colored. In the summer, when the ecliptic is low, the horizon light frequently blends with the zodiacal band.

MAJOR MACGREGOR'S EKOWE POCKET HELIOGRAPH.

VERY handy and portable form of heliograph has recently been designed by Major Macgregor, of the ...th Regiment. The inventor was led to consider the subject from the success which attended his efforts to communicate, by means of sun-signalling, from Fort Ekowe to the Tugela, in Zululand, last year. The means then at hand consisted only of a looking-glass, in the possession of an officer's servant, which, by suitable arrangement, did the work very well over about 27 miles of country.

From Ekowe, over a distance of 10 miles, Major ... sent messages by means of a shaving glass held in one hand, shutting off the sun with the skirt of his coat in the other.

C, are unscrewed. The two mirrors lie face to face, and the legs and upright of stand (with sight arm folded down) lie parallel to one another, the whole fitting into a leather case 13 inches long, 3½ inches wide, and 1½ inch deep. The instrument weighs two pounds.

The instrument is used in the following manner:—

When the sun, S, is in front—that is, towards the distant station, the heliograph is set up with the sight vane (enlarged sketch seen to the right of fig. 1) in the general direction of the distant station, and the mirror facing in the same direction (as shown by fig. 1).

The eye is then placed as close as convenient to the back of the mirror, and the latter looked through at the centre hole; at the same the V of the sight vane, E, is set in line with the distant station.

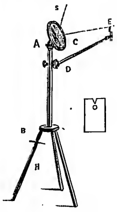

FIG. 1.

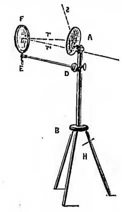

FIG. 2.

The present instrument is extremely portable, cheap, and not liable to get out of order.

The following is a description of the apparatus:—

A B is a metal stand; H, H, H, three legs screwed into base, B; A, a ball and socket, carrying a very short arm, to which is fixed a circular mirror, C, 3 inches diameter, having a small hole pierced through centre of the backing, and the silvering removed at that point. D E is a light arm, about 8 inches long, movable on a ball and socket at D, and clamped by a screw behind D.

F is a circular mirror similar to C, having a straight arm 2 inches long, which fits into a socket at E, the socket being movable on a hinge. The mirror, F, can be removed at pleasure, and the socket, E, turned so as to stand upright, to form a "sight vane" when the sun is in a certain position.

To pack up the instrument, the legs and mirror,

The mirror and sight arm are then so manipulated that the dark spot, cast by the unreflecting centre hole, is thrown on the bottom of the V, in the sight vane, whilst, *at the same time*, the centre hole, bottom of V, and distant station are in one straight line. Thus, the "flash" is directed on the distant station.

Signalling is carried on by using the Morse alphabet of "dots" and "dashes," which is effected simply by interposing and removing the hand, a note book, piece of board, &c., smartly between the sight vane and the surface of the mirror. By this means letters can be sent as fast as the eye can read.

In military signalling it has recently been decided to signal by obscuration instead of by flashing, which renders this instrument rather more handy than if "flashing" only were used.

When the sun is not in the direction of the

32

OPTIC TELEGRAPHY.

A new mode of optic telegraphy has been invented by M. Mercadier which is said to greatly increase the amount of light now used for intermittent luminous signals in ships, lighthouses, &c. The common method is that of bringing a movable diaphragm before a steady source of light. Thus the light is not utilised during eclipse, and it has been estimated that in ordinary systems 65 per cent. of the light is lost (in lighthouses sometimes 90 per cent.). M. Mercadier, according to the *Times*, has lately proposed a new plan, the essence of which lies in varying the source of light, making it flash up to its maximum at one moment, and reducing or extinguishing it at another. This can be done either by promptly varying a supply of oxygen to a low flame or by varying the supply of combustible gas. M. Mercadier describes an arrangement of the former kind, in which he uses a simple petroleum lamp of M. Duboscq; it has a round wick (which does not pass beyond the containing cylinder), and in the centre rises a thin vertical tube, debouching a little below the plane of the wick. This tube admits the oxygen coming from a reservoir. The mode of admission is by pressure with the finger on a key, like that of a Morse apparatus; this has the effect of momentarily releasing a caoutchouc tube (by which the oxygen is conveyed) from the pressure of a clip. The flame then brightens. On taking the finger off, the supply of oxygen is stopped again, and the flame is reduced to very small size. This system, M. Mercadier says, has been adapted to apparatuses of optical telegraphy, and has given good results. We are very curious to learn how the inventor proposes to solve the same problem with the electric light.

PNEUMATIC TELEGRAPHS.

The Engineer March 5 1880

The system of forwarding telegrams by means of pneumatic tubes has been, really speaking, of slow growth, and beyond its adoption by the old Electric Telegraph Company in the United Kingdom, its spread has been slow in the extreme. Few places on the Continent have adopted it, and about its latest introduction has been in New York. Its early history and introduction are not uninteresting, especially when it is considered that, from its success, many and strenuous efforts have been subsequently made to establish a railway system under similar mechanical arrangements.

The Electric Telegraph Company, about the year 1856, had occasion to establish a purely delivery station at Lloyd's, and from a variety of reasons it was found too expensive to establish a regular telegraph station with wires, instruments, and clerks. Mr. Latimer Clark, who was then the engineer to the company, suggested that by the laying down of a small leaden tube, and the employment of small engine power, air might be compressed, and employed to force the messages through, inclosed in suitable carriers. The idea thus suggested was put into practical operation, and was successful; and it may be remarked that, with few variations, the original system as introduced by Mr. Clark remains in force to the present day. The requirements at that time were simply for the speedy delivery of telegrams, and the tube being found quicker than even wire or hand, its use was extended, until a further development took place, when it was found that by the use of an exhausting pump, or a vacuum, messages could be received at the central station as well as forwarded from there. This alteration occurred some years later, when Mr. Cromwell Varley became Mr. Latimer Clark's successor as engineer to the Electric and International Telegraph Company. The extensions then became more rapid, and previous to the acquisition of the telegraphs by the General Post-office, a large system of pneumatic communication had not only been established in the city of London, but also in some of our provincial towns.

The tubes employed were of lead, 1½in. diameter, enclosed in ordinary iron piping—where the business was large a pipe of 2¼in. was subsequently used—and with the engine was employed a "container," so that a quantity of air might be stored, as that was found necessary when several tubes were at work simultaneously. At the time of the transfer, and for some few years subsequently, the Central Telegraph Station was at the old Telegraph Company's headquarters in Telegraph-street, and remained there until the arrangements were completed for their transfer to the new General Post-office at St. Martin's-le-Grand, but the change in the pneumatic system did not take place until a subsequent period. Previously, however, a double line of pneumatic tubes on the Siemens system—adopted in Berlin—with iron tubes, had been laid down between Telegraph-street and Charing Cross, with intermediate stations at St. Martin's-le-Grand and Temple Bar. These tubes were 3in. diameter, and the stations fitted with a peculiarly clever switch arrangement for the interception and forwarding "carrier."

The change to the New General Post-office involved an entirely reconsideration of the whole question of pneumatic transmission, and when the special stations selected with regard to public and postal convenience were decided on, elaborate experiments were entered into as regards the question of speed of transmission, amount of motive power, size of pipes, and various other details; the result is to be seen at the present time, and but few alterations or amendments have been found necessary. Indeed, the system of tubes as then planned has been found so generally equivalent to the work required, that but few extensions have been made, the most important being that to the Houses of Parliament, which extension by the way was originally contemplated when the Siemens plan was first adopted. It was decided to do away with all the small gauge tubes, and adopt entirely the 2¼in. tube, which, after many experiments, was found to be the best size in every respect.

The plan adopted in this country from the outset and subsequently adhered to has been that of the "radial" system, whilst on the Continent the "circular" arrangement has been preferred. That is to say, it has been considered here—especially in the companies' days when competition was so rife—that speed, and rapidity of delivery were everything. Each important delivery and receiving station was in direct communication with the central station, so that no time should be lost in transmission through other stations, and where the importance of the stations was found of sufficient greatness two tubes were laid, one for sending and the other for receiving messages. On the Continent, however, it is considered amply sufficient to have a circular line with a certain number of stations on it. Trains of "carriers" with one labelled for each station are despatched at regular intervals, and their contents being taken from or added to at the several stations, return to the central station again. This may conduce to regularity, but certainly not to speed. The radial system as adopted by us has invariably been found to be successful, and it continues to give complete satisfaction.

The system of the pneumatic tubes now in use by the General Post-office is about twenty-five and a-half miles in length, of which about six and a-half miles are in provincial towns, the remainder being in the metropolis; the longest tube is that from the central station to the Houses of Parliament, whilst the remainder are almost entirely confined to the City, the longest of these being that to Lower Thames-street, which is almost exactly one mile in length; this is the only tube in the City which has an intermediate station in it. There are many stations close to and there are also many in connection with the central station and its various departments; indeed, these and the tubes in the building inside are so many that they occupy nearly a mile in length.

There are few who witness the expediting of messages through the tubes at the central station who are aware from the simple action of the messenger boys engaged in forwarding, the amount of care and mechanical skill which has been called for, not only in laying the pipes, but also in the arrangement for receiving and forwarding messages. If it were not for extreme care, the soft lead tubes would offer obstacles to the carrier containing the messages, such as to delay if not prevent its arrival at its destination. But science and skill have so far triumphed that the work at the end of the tube is so simple and mechanical that a very small boy can learn in a few moments.

At the receiving, or stations other than the central, all is simple and there is really nothing to be seen. At the central station, however, everything is combined, and we have there the heart of the system, which gives life and vitality through its tubular conductor to the outlying arteries. Taking the general pneumatic system as seen from one's view at the central station, we can see that messages are transmitted by the motive power of air admitted by a peculiar arrangement of valve into a conducting tube, and that the motive power is produced by the action of steam. It may be within the recollection of our readers that a description of the special engines, designed and constructed by Messrs. Eastons and Anderson, appeared some time since in our columns. The engines, it is only necessary to say here, consist of three 50-horse power condensing engines on the compound principle, and we believe it may be safely stated that there cannot be seen anywhere in London a prettier sight than the engine room with all its bright work and cleanliness, reflecting credit not only to the designer, but to those who have the constant task of keeping it as it ought to be. To each engine are attached two air-pumps for either compressing or exhausting air, and the valves connected with these pumps are of such excellent design that the duty of the pumps can be changed without the stoppage of the engine. From the engine-room in connection with the air-pumps are conducted two large mains to the central gallery, the one for the compressed air, the other for the exhausted air; the capacity of the former is 285 cubic feet, that of the latter 439 cubic feet, a greater capacity being always required for the exhaust tubes; but the absolute requirements of such mains is not a stringent necessity; they have been adopted in order to provide an even flow of air, so that pulsation should not occur.

The sight, as we have mentioned, the visitor sees is a long row of lead tubes, terminating in brass valves. These tubes are arranged in the following manner:—At one end of the row are all those which are especially and only engaged in forwarding messages; at the other end are those which are only engaged in receiving messages, whilst between the two are those tubes which alternately receive or send, or are used indiscriminately for either purpose. For the end tubes a single sluice valve is fixed, for the middle a double sluice valve, whose working is simplicity itself; these valves are of considerable merit, and are the design of Mr. Willmott, who has been connected with the pneumatic system from its early days. The messages are enclosed in "carriers," which differ but little from those originally constructed. The carrier as at present improved upon consists of a central tube of wood fibre prepared in a peculiar way—formerly this tube was of gutta-percha—surrounded by a jacket of felt, at one end projecting, at the other protected with buffers of the same material, the central portion being of larger diameter, acting as a piston fitting close to the tube; the loose end also acts as a piston when inflated by the air pressing on it. Between the inner tube and its jacket is a broad elastic band, which on being stretched allows the messages to enter, and on its relaxation keeps them firmly in their place, preventing them from falling out.

It is hardly necessary to explain that when the carrier is placed in the tube, and compressed air is admitted, it is immediately propelled towards the distant end, where it discharges its freight of telegrams; and when a carrier is inserted at the receiving end of the tube, the signal being given, the exhaust is applied, the carrier progresses driven by the incoming air. It is strange to watch the rapid incoming and outgoing of these carriers consequent on the receipt of the various electric signals, for be it known the traffic through these tubes is regulated on the block system, and, indeed, it is not unlike a well-worked railway system.

The amount of air pressure used is as a rule about 11 lb. to 12 lb. per square inch for forwarding, and about 8½ lb. for receiving or vacuum, whilst the pressure of steam in the boilers is from 55 lb. to 60 lb. The engines are not all used at the same time, two engines only are at work during the day from nine a.m. until five p.m., and one from five p.m. until nine a.m. next day. Whilst the two are at work, one is occupied in compressing air, the other in producing a vacuum; and at night time when the single engine is at work, one pump compresses, the other exhausts. Every month an engine is relieved from work, and the spare one takes its place, during which time the standing engine is overhauled.

From the variety of curves and gradients of the pipes it is difficult to arrive at any just comparison of the speed of the various tubes, but there can be no question of the immense advantage in the rapidity of delivering messages within a limited radius by pneumatic tubes. Even with the tube to Thames-street, a mile in length, the time occupied is less than three minutes, and with one about half a mile in length only one minute. As we have before remarked, the system of lead tubes has found universal favour with us, and when once laid carefully and free from fault, it should last for an almost unknown period free from any inherent accident or fault; the only cases of interruption to the passage of carriers are due to external causes from the carelessness of men opening the streets. A pick breaks the outer iron pipe and makes a dent in the leaden tube, causing an obstruction. When such an event occurs, which is extremely rare—hardly one per annum—the damage is soon found and remedied.

IMPROVED HELIOGRAPH OR SUN SIGNAL.

By TEMPEST ANDERSON, M.D., B.Sc.

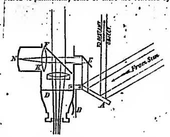
(Read before the British Association, Aug., 1880.)

THE author claims to have contrived a heliograph, or sun telegraph, by which the rays of the sun can be directed on any given point with greater ease and certainty than by those at present in use.

When the sun's rays are reflected at a small plane surface considered as a point, the reflected rays form a cone, whose vertex is at the reflector and whose vertical angle is equal to that subtended by the sun. Adding to the size of the mirror adds other cones of light, whose bounding rays are parallel with those proceeding from other points of the mirror, and only distant from them the same distance as the points on the mirror from which they are reflected. Hence increasing the size of the mirror only adds to the field to which the sun's rays are reflected a diameter equal to the diameter of the mirror, and this at any distance at which the sun-signal would be used is quite inappreciable. Adding to the size of the mirror adds to the number of rays sent to each point, and hence to the brightness of the visible flash, but not to the area over which it is visible.

By the author's plan, an ordinary field-glass is used to find the position of the object to be signalled to, and to it is attached, in the position of the ordinary sunshade, a small and light apparatus, so arranged that when the mirror is turned to direct the cone of rays to any object within the field of view of the glass, an image of the sun appears in the field, at the same time as the image of the distant object, and magnified to the same degree, and the part of the field covered by this image is exactly that part to which the rays are reflected, and at which some part of the sun's disc is visible in the mirror.

A perfectly plane silvered mirror, A, takes up the rays of the sun, and when in proper position reflects them parallel with the axis of D, which is one barrel of an ordinary field-glass. The greater part of the light passes away to the distant object, but some is taken up by the small silvered mirror, E, which is placed at an angle of 45° to the axis of D, and reflected at a right angle through the unsilvered plane mirror, F, and the convex lens, K, by which it is brought to a focus on the white screen, H, which is placed in the principal focus of K. The rays from this image diverge in all directions, and some are taken up by the lens, K, and restored to parallelism; some of these are reflected by



the unsilvered mirror, F, down to the field-glass, D, and if this is focussed for parallel rays, as is the case in looking at distant objects, an image of the sun is seen projected on the same field of view as that of the distant object. As the mirrors, E and F, are adjusted strictly parallel, the rays proceeding from F into the field-glass are parallel and in the opposite direction to those going from the mirror, A to E, which form part of the same pencil as those going to the distant object. Hence the image of the sun seen in the field exactly covers the object to which the sun-flash is visible, and in whatever direction the mirror, A, is moved so as to alter the direction in which rays are reflected to the distant object, and the angle at which part impinge on E and are reflected through the lens, K, the image visible in the glass moves in the same direction. Several attempts to produce this result were made by the use of mirrors and prisms, before the lens, K, was introduced, but they all failed. It was easy to make the image of the sun cover the object when the two occupied the centre of the field of view, but directly the mirror was inclined so as to direct the rays not strictly parallel to the axis of the field-glass, the apparent image diverged generally in the same direction along one co-ordinate, and in the opposite along one at right angles to it, so that nowhere, but in one line across the field, did the image lie in the desired position. The mirrors, E and F, are adjusted parallel once for all, by noticing the position on a screen of the small spot of light reflected from the front of F as the light passes from E to K. The mirrors are moved by the adjusting screws till this spot has, to the bright reflection from the mirror, A, the same relative position that the centre of mirror, F, has to the mirror, A.

In actual use the field-glass is first fixed in position pointing to the object, either by holding steadily in the hand, or better by a clamp attached, by which it can be screwed into a tree or post, or fixed in the muzzle of a rifle. The instrument is turned on the barrel of the glass till the sun is in the plane passing through the two axes of the instrument, and the mirror, A, is turned till the bright image of the sun is seen on the screen, H, through a hole left for the purpose in the side of the tube. On looking through the glass the sun's image is seen, and by then slightly rotating the instrument or moving the mirror, is made to cover the object. The mirror, A, is connected not directly to the body of the instrument, but to a lever, B, on which it works stiffly, so as to retain any position in which it is placed. Lever B works easily and has a limited range of motion, to one end of which it is pressed by a spring; slight pressure with the finger moves it and its attached mirror, so as to throw the light on and off the object in a succession of long and short flashes by which letters and words may be indicated. Flashes may also be given by moving the instrument if held in the hand.

The above instrument answers well for all positions of the sun except when very low behind the observer's back. For this case another mirror is provided by which the light is reflected on to the mirror, A. Messrs. T. Cooke & Sons, York, are sole makers of this instrument.

Dilatation of Bodies by Electrification.—At a recent meeting of the French Academy of Sciences, M. E. Duter described some experiments tending to show that in certain cases electrification changed the volume of bodies. A large thermometer tube is filled with water and coated outside with tinfoil. The tube then forms a Leyden jar or condenser, the water being the interior conductor, the foil the exterior conductor, and the glass tube the insulator. A platinum wire inserted into the water inside acts as an electrode or charging rod. As soon as the jar is electrified the water is seen to sink to a lower level, at which it remains until the jar is discharged, when it immediately regains its former height. Since, in a condenser electricity only resides in the insulator, it is natural to conclude from this experiment that the glass itself is dilated, and this inference is supported by the fact that whatever be the nature of the armatures, tinfoil, water, saline, or mercury solutions, the same apparent contraction of the internal liquid is observed. In order to remove all doubts M. Duter modified the apparatus by placing the Leyden jar in an envelope of closed glass, terminated also by a thermometric stem and filled equally with a liquid conductor. In this arrangement the liquid of the internal reservoir formed the interior armature of the condenser, and the liquid of the envelope formed the exterior armature, the glass tube forming, as before, the insulator. This glass tube ought, if the inference be correct, to enlarge itself by electrification. The result was that while the inner liquid sank the outer liquid rose to an equal amount, thus proving the accuracy of the inference. As soon as the apparatus was discharged, the original levels were restored. The conclusion is that the internal capacity of a Leyden jar and the external volume are increased by charging it with static electricity. Temperature cannot cause this change since the effect is immediate on charging and discharging. Electric pressure cannot cause it, because it would be the same on both sides of the dielectric, and a diminution of volume would be the result. It is not due to the polarity of the armatures, for on reversing the poles the effect is the same.

M. Jamin pointed out that the first observation of M. Duter, namely, that the internal volume of a Leyden jar is increased by charging it, was noticed by M. Govi about ten years ago, in the transactions of the Academy of Turin; but that he had not seen as M. Duter had done, that the exterior volume also increased.

Tel Jour Nov. 1. 1878

Elongation of a Conductor traversed by a Current.—M. Blondlot has presented to the French Academy of Sciences an account of some experiments undertaken with a view to prove whether or not there is really an elongation of a wire when a current passes in it, as Edlund and Streintz have believed and Wiedemann has denied. This method is designed to distinguish more clearly than heretofore between the effect due to heating and that due to the current. The principle of it consists in intercalating a thin metal ribbon in the circuit, by means of stout soldered connections. Any effect due to heating will dilate this ribbon both longitudinally and transversely, so as to increase its bulk without deforming it. But the current effect, if it take place, will do so unequally in the two directions, and will consequently deform the ribbon. Any misshaping of the metallic band or of figures traced on its surface ought therefore, M. Blondlot reasons, to be due to the current, and if there be none, such a direct mechanical action of the current does not exist. With the current from ten Bunsen cells no elongation could be detected, although the arrangement was capable of showing an elongation of 0·00000025m. per metre. Ribbons of brass, German silver, and other metals were experimented on, but with the same negative result.

Tel Jour June 15 1878

Action of Electricity on Flames.—Memoir by M. V. Neyreneuf. (Extract by the author).—There has been demonstrated the existence of an electric wind in placing a flame near an electrified point. The experiment is in reality complex, and depends, *inter alia*, upon the nature of the fluid we employ. A flame may be considered as a very good conductor; produced at the extremity of a glass tube well insulated and placed before a point, it attracts the molecules of air that surround this point, and in this manner the wind results. It is susceptible itself of attraction, and with inverse proportionality to the distance of the point; there should therefore exist a certain distance at which the wind acquires a maximum intensity. It is this which I have to make known. If the flame is produced at the extremity of a metallic jet in communication with one of the armatures of a Holtz machine, whilst the point communicates with the other, the electric wind is generally much more intense, but the effects are complex, and follow the relative arrangement of the point and of the flame. Matters arrange themselves always as if the electricity were really propagated in a direction from positive to negative; also a positive point repels the flame, while it is attracted by a negative point. With a Bunsen flame we do not obtain sensible repulsion.

Tel Jour, Dec 1 1877

Nature of the Electric Spark in a Gas.—From researches which he has made, M. Cazin concludes that the electric spark in a gas is due to incandescent gas particles, and solid and liquid particles. The gas particles give a bright line spectrum, and the solid and liquid particles a continuous spectrum. They are derived from the gaseous medium and the electrodes. As the pressure of the gas is increased, the solid and liquid particles become more abundant, the continuous spectrum intensifies, and the bright line spectrum seems to dilate, till eventually the two spectra flow into each other, and blend in one continuous spectrum.

By experiments on the length of the electric spark in different gases at the ordinary atmospheric pressures, MM. Warren de la Rue and Hugo W. Müller find that the length of the spark under the ordinary pressure is longest in hydrogen, nitrogen, oxygen, and carbonic acid. It is nearly twice longer in hydrogen than in air. The spark in air between a point (positive) and a plate (negative) with the battery employed (8,040 chloride of silver cells) was about 0·34 inch in length; in hydrogen the length was 0·60 inch. The length of the spark does not appear to depend on the specific gravity of the gas, but rather on its viscosity.

Tel. Jour Dec 15 77

Dilatation of Wires by the Electric Current.—It has been thought that the electric current dilates the wire through which it is passing to a greater degree than that due to its heating effect, and results have been obtained supporting the idea. Recent experiments of M. Exner, however, on wires of platinum, copper, iron, and steel, lead him to believe no such dilatation exists. The experiments were made by heating the wires to a steady temperature by the current, and measuring both the dilatation and resistance. By means of the resistance results it was possible to raise the wires afterwards to exactly the same temperature by means of an ordinary source of heat. A comparison of the dilatation when heated by current and when heated otherwise, showed no extra dilatation due to the current.

ON A NEW FUNDAMENTAL LAW OF ELECTRO-DYNAMICS.

Till quite recently Weber's law was generally accepted as a fundamental law for all electrical phenomena, embracing the laws of static electricity, and electro-dynamic as well as induction phenomena. It is based (as is known) on the assumption, that two particles of electricity which are in relative motion exert forces on one another, which are different from the forces exerted by the same particles on each other when at rest. The first objections against Weber's law appear to have come from the English side. In Thomson and Tait's Handbook of Theoretical Physics, the Weber hypothesis is cited as an example of a theory which is rather injurious than useful, because Weber's conclusions are in contradiction with the conservation of energy, and because the supposition of two different electric fluids cannot possibly correspond to fact. The English views were adopted and advocated by Helmholtz in a work published in 1870. This work was the beginning of a long controversy with regard to Weber's law, in which various *savants* took part; a controversy which, indeed, still continues.

Recently M. Clausius has sought to replace Weber's law (which he rejects, as contrary to fact, on grounds independent of those of Helmholtz), by another. He starts from representations which differ in essential points from those hitherto common. He supposes that the electro-dynamic action of two moved particles of electricity on each other is by means of matter existing between them. Consequently, it is not necessary that this action depend merely on the relative motion of the particles, but it may also be influenced by their *absolute* motion: since the moved particles behave ever differently with regard to the medium between them, acording to the kind of motion. In this reprerentation, the supposition is no way unnatural, that the direction of the electro-dynamic force does not coincide with the connecting line of the particles. On the basis of this supposition, M. Clausius has given, for the action between two electric particles, general expressions, from which all forces exerted by galvanic currents on each other, and inductive actions, may be deduced. Specially as regards the force which one current-element is subject to from another, M. Clausius obtains an expression for it, which is somewhat more general than Ampère's expression for the same force. Clausius' expression passes into that of Ampère if we give to a certain constant the value 1. In the action of closed currents on one another, which it has only been possible to investigate experimentally hitherto, that constant goes quite out from the result. In this case, therefore, the new law of Clausius agrees perfectly with experience. With regard to that undetermined constant, M. Clausius expresses the conjecture that its value is equal to *nil*, because through this supposition the fundamental equations are brought to their simplest form.

M. Clausius has then further examined the question, whether the new law is in harmony with the principle of conservation of energy. He finds that this is the case if we assume that in each current-element there are equal quantities of positive and negative electricity, and if we take into account not only the action of the electrical quantities of like name, but also those of unlike name. The members connected with the hitherto undetermined constant do not, of course, range under the law of the conservation of energy, but disappear for closed currents. If that constant be equal to *nil*, then even for the elementary action the agreement with the law of conservation of energy is perfect.

In conclusion, M. Clausius gives a further expression for the elementary action between two current particles. It differs from the first, only in the parts by which the action of closed currents is not affected. The further conception (in addition to the one above referred to, and likewise differing from that hitherto common) underlies this expression, that the force which one particle exerts on a second is not similar to the force which the second exerts upon the first.—*Der Naturforscher.*

Tel Jour July 15 77

On a New Fundamental Law of Electro-dynamics. By R. Clausius.—In explaining the phenomena of electro-dynamics, W. Weber has stated a law with respect to the mutual effect of two electric particles when in motion. Let e and e' be the two particles, and r their distance apart, which is to be regarded as a function of the time t. According to Weber, these particles repel each other in a manner represented by the following formula, in which c is a constant:—

$$\frac{e\,e'}{r^2}\left[1 - \frac{1}{c^2}\left(\frac{dr}{dt}\right)^2 + \frac{2}{c^2}\,r\,\frac{d^2 r}{dt^2}\right]$$

Helmholz has raised certain objections to this formula, and the author, upon grounds quite distinct from those upon which Helmholz has based his objections, has come to the conclusion that the formula in question does not represent the actual facts. The author's investigations have led him to the statement of another law in this case.

In starting with the idea that the electro-dynamic action upon each other of two moving electro particles takes place through the medium which separates them, we must not assume that this action is dependent merely upon the *relative* motion of the particles, but an influence must be attributed to the *absolute* motion of each particle; for example, if two electric particles move in a parallel direction and with equal rapidity, and are as a consequence equally at rest, they, nevertheless, may exercise an electro-dynamic influence upon each other, for as regards the intervening medium they behave otherwise than as particles really at rest.

The latter part of the paper is devoted to the development and statement of the formulæ used to express the new electro-dynamic law put forward by the author.

ON THE TEMPERATURE OF THE ELECTRODES IN THE INDUCTION SPARK.

When discharges occur between electrodes, a very various behaviour of the latter is noticed, and heat actions especially are found to preponderate on one side or other, according as the discharge is in one direction or the opposite. Mr. Hermann Herwig (*Pogg. Ann.*) recently thought he might arrive at a more adequate explanation of the case of the induction spark passing in free air if he determined exactly the influence of an independent heating of one electrode on the phenomena. Such heating, by supplying beforehand a certain portion of that heat which otherwise the discharge must effect, seems specially fitted to throw light on the nature of the relations in question.

In carrying out this plan, the ends of the secondary coil of a large Stöhrer Induction apparatus were connected through a sensitive mirror galvanometer, and then brought in a symmetrical manner to the two halves of a severed platinum wire, which were placed horizontally one over the other, and crossing at right angles, being separated by a small layer of air. The free ends of the platinum wires passed over insulated pulleys, and were stretched with weights, while the other ends were connected with the induction wires through a commutator, by means of which the upper wire could be made the positive or negative electrode for the induction currents always going in the same direction. The upper platinum wire could then, by means of mercury cups, and without any disturbance, be inserted in the circuit of a special battery, by means of which it could be heated to the commencement of a weak red glow. The direction of the current used for heating was indifferent for the results of the experiment.

With these arrangements, the effect on the galvanometer of a single making and breaking current was each time observed; first, when both the wires were cold; and next, when either the positive or the negative wire was heated. It is evident that the galvanometer-effect with such induction sparks is also dependent on other circumstances; as on the softness of the electrodes, which in later discharges is greater than in earlier. Hence, a definite explanation could only be expected from numerous suitably arranged experiments; and the mode of proceeding was, that, in connected series, ten experiments were made with cold wires, then ten with glowing of the positive, ten with glowing of the negative, again ten with cold wires, ten with negative glowing, ten with positive glowing, and lastly ten with cold wires. With cold wires, the upper was alternately positive and negative. The average values obtained from several hundred experiments are contained in the following table:—

Separation of the wires.	Deflection. With cold wires.	Deflection. With positive heated.	Deflection. With negative heated.
¼ mm.	126·5	261	337
[illegible] „	55·5	122·5	201·5
[illegible] „	40	55·5	175
1½ „	5	19	82
4 „	4	15	30

"Without attaching too great value to the numbers," says Mr. Herwig, "it may thus be affirmed with certainty that a vigorous heating of the one electrode lets greater quantities of electricity from the action of certain electro-motive force of induction pass over, and that this holds preeminently for the negative electrode. The first part of this result might have been expected, as both the tearing loose of metallic particles and the driving of charged air particles out from an electrode already highly heated must take place more easily; it also distinctly shows that both electrodes essentially participate in the discharge. Of much greater importance, however, is the second part, according to which the negative electrode, under the same favouring influence, gives much more abundant quantities of electricity than the positive. Further, the above-mentioned variability attaching to galvanometer actions in such experiments mostly ceases when the negative electrode glows, and secondly it is only in the case of the glowing of the negative electrode, with short distances, that a slight galvanometer action is also sometimes obtained with the closing induction current.

"Thus, what earlier experiments made probable enough, is undoubtedly confirmed (it seems to me) by these experiments, in a more direct manner, that, namely, even in the induction spark, which passes in free air, *the negative electricity is more easily put in motion.* For the gas discharges of the Holtz machine, this has been likewise proved by MM. Wiedemann and Rühlmann."

With the assumption, now no longer arbitrary, that in the separation of charged metal or gas particles from the electrodes the negative charge is more easily carried away, M. Herwig points out that the insufficiently explained one-sided action of such discharges becomes readily intelligible. In general, apart from various conditions modifying the phenomenon, experience teaches that the negative electrode shows the greatest production of heat, when a discharge occurs discontinuously with short impulses; when, on the other hand, the discharge is of a more regular, continuous character, the heat action preponderates at the positive electrode. Now the heat action is chiefly at the place where the electric motion is terminated, or where the electric equalisations specially occur. With the discontinuous discharge the greater mobility of the negative electricity acts so that a stronger backward equalisation of the electricity takes place at this electrode, and, besides, the equalisation must also occur in the portion of air in the neighbourhood of the negative electrode, because, according to Wiedemann and Rühlmann's observations, the more difficultly discharged positive electricity is driven forth with greater velocity from its electrode.

With the more continuous discharge of the Voltaic arc, on the other hand, the interrupting layer may be regarded as pretty conducting, so that the greatest heat effect occurs in the place of the greatest resistance, that is, in this case, at the positive electrode.

Effects of Heat on Voltaic Circuits completed by an Electrolyte. By M. Hellesen.

I. M. du Moncel has shown, that if one of the plates of an electrolyte is heated, there is a thermo-electric action causing a current to be developed, for which the heated plate forms the positive pole. This may become very strong, if the arrangement is such as to maintain the liquid round the two plates at very different temperatures. M. Hellesen connects two test-tubes near the top by a narrow tube, fills them with saturated solution of sulphate of copper, and fixes the copper electrode in one near the top, in the other at the bottom. Then he heats with a spirit lamp the test-tube whose electrode is near the top. A considerable current is obtained, and this electrode is quickly covered with copper. A simpler arrangement is, to fix on the edge of a vessel containing sulphate of copper solution a plate of copper curved so as to touch the surface of the liquid on one side, while on the other it presents, outside of the vessel, a surface which may be heated. The other electrode is immersed at the bottom of the liquid and connected by covered wire with the first; thus a strong current may be had. In these arrangements, the heated parts of the liquid tend to remain at the surface. Using magnetic helices of copper tubes, in which might be made to circulate cold water and super-heated steam, magnetic effects might be obtained (M. Hellesen thinks), which would explain the magnetic state of the globe in virtue of the unequal temperature of the seas. II. If an electrolyte be formed with the smoky flame of a paraffine candle, and a current be sent from 40 Leclanché elements or 30 of bichromate of potash, a strong arborescent deposit of carbon first forms at the end of the negative wire, the branches tending to rise in the direction of the flame, and to regain the positive wire. In a few seconds, carbonised threads, slightly arched, come to be deposited on the latter, also tending to rise with the flame. If you bring the two sets of deposits near each other, there pass a series of brilliant sparks. III. If for the short wire, connecting the anvil of the contact-breaker of a Ruhmkorff coil with the condenser, there be substituted a long wire wound parallely with another on a second bobbin, one may observe, when the ends of the second insulated wire are placed a short distance apart, a pretty strong spark, which can only come from the discharge of the condenser; for it can be produced with quite short wires not wound in helix, it is not influenced by a magnetic core placed in the second bobbin, and the inductor current of the apparatus does not pass into this second bobbin. On the other hand, it increases with the size of the condenser, and depends on the nature of the insulating plates of the latter; the strongest effects being with mica. This spark has in some cases had sufficient tension to traverse several millimetres of air, though only one Bunsen element (middle size), a coil of moderate dimensions, and a secondary wire of 10 metres, have been used.

ON THE

ABSOLUTE ELECTRO-MAGNETIC UNITS OF RESISTANCE AND ELECTRO-MOTIVE FORCE, WITH SUGGESTIONS FOR THEIR RE-DETERMINATION.

At the late British Association Meeting at Belfast a very important communication with the above title was made to Section A by Professor G. Carey Foster.

Kirchhoff and Weber were the first to devise methods of measuring electrical resistance in absolute electro-magnetic measure. Subsequently, Sir W. Thomson suggested a method for the same purpose to a Committee of the British Association, by whom a series of measurements were carried out at King's College in 1863. The results of these experiments have been accepted throughout England, and the B.A. unit has passed into general use as the "Ohm." In Europe, however, its employment has been but partial, and its accuracy has lately been questioned by Continental physicists. M. Kohlrausch has lately, by a most careful series of experiments, determined an absolute unit which differs considerably from the ohm, and in his paper (which has been translated into the *Philosophical Magazine*) he assigns his reasons for supposing the ohm to be wrong. Still more recently, Professor Lorenz, of Copenhagen, has by another method made a determination which differs from both the preceding.

The extent to which the three sets of experiments differ is shown by the following comparison: the absolute resistance of a Siemens mercury-unit is—

According to the Brit. Assoc. Committee	...	0·9537
,, Kohlrausch	... ...	0·9717
,, Lorenz	... ...	0·9337

Thus, although the results are not concordant, the value obtained by the Committee is intermediate between those given by the other two determinations. With these discrepancies in the results, it is obviously desirable that this most important physical measurement should be repeated with all possible precautions to ensure accuracy.

Foster's method consists (like any other) in determining the ratio of the electro-motive force to the strength of the current produced by it in a given conductor: and then, since—

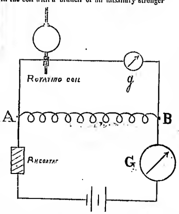
$$\frac{E}{C} = R,$$

the resistance of the conductor is determined.

For this purpose a large coil of covered copper wire, like a hoop placed vertically, is made to rotate about a vertical axis, so as to have a certain electro-motive force E generated in it by the horizontal component of the earth's magnetic force. During each half-revolution beginning and ending with the plane of the coil at right angles to the magnetic meridian, the mean value of E is—

$$\frac{2aH}{t},$$

where a is the effective area of the coil, t its time of revolution, and H the earth's horizontal intensity; but during successive half-revolutions the sign of E is alternately positive and negative. The ends of the wire of the coil are connected with a commutator on its axis (as in an ordinary Delezenne's circle) which causes the current in all external portions of the circuit to flow in only one direction. This being arranged, all that would be wanted, in order to know the resistance of the wire of the coil, would be to measure the strength of this current, and calculate the electro-motive force by observing the speed of rotation. But it is plain that the resistance so calculated would include the resistance of the commutator, which is variable and wholly irregular, so some modification is necessary which shall entirely eliminate this source of error. Prof. Foster manages this by applying Poggendorff's method of measuring E.M.F., that is, by stopping all current in the coil with a branch of an auxiliary stronger



current. A constant battery (shown in the diagram) has its circuit completed through a Siemens unit, a standard coil, or other conveniently-mounted resistance, A B, which it is desirable to know in absolute measure. A certain difference of potential exists between the ends of the wire A B, and this can readily be altered by changing the resistance of other parts of the circuit till it is precisely equal to the electromotive force generated in the coil when revolving at some constant rate. There is a delicate Thomson's galvanometer, g, in the coil circuit, which shows when the two differences of potential are equal by the absence of all current through it; and when this point has been attained, the battery circuit is totally unaffected by its connection with the coil. The strength of the current in A B is now to be very carefully measured in absolute measure by an accurate absolute tangent-galvanometer, G; this current is produced by an electro-motive force E (which we have arranged to be equal to the difference of

July 22 1875

Journal de Physique, June, 1875.

Note on the Pressure of Electricity and on Electric Energy.—M. Blavier.—Hardly suited for abstraction.

On the Flow of Liquids.—M. Isarn.—The author shows, by some experiments, that in the phenomenon of contraction of a liquid vein, one cause is, superficial tension acting like an elastic ring round the jet where it quits the vessel. In one experiment he varies the superficial tension by action of electrolysis. A vein of mercury is made to flow through a narrow tube which is immersed in acidulated water, connected with one pole of a battery, while the mercury is connected with the other pole. With suitable pressure, the flow being *nil* in normal conditions, it appears either in drops, or with a limpid portion when the current passes so that the vein is positive. On breaking the circuit, the flow ceases, as if one had turned a cock. Again, if the liquid already flow with a limpid portion, this portion is suddenly elongated when the vein becomes positive. Lastly, if the vein be made negative, the phenomena are reversed, so that the limpid portion contracts successively, in the passage from + to zero, and from zero to −; and we may have continuous flow when the vein is positive, flow by drops when it is in a neutral state, and complete cessation of flow when it becomes negative. These phenomena show that the positive mercury, *i.e.*, oxidised superficially, has a weaker superficial tension, and that this tension returns to its normal value when the mercury is deoxidised. M. Isarn has noticed the same thing in the sinking and rise of an areometer plunged in mercury, when the surface of the latter, covered with a layer of acidulated water, is made successively positive and negative by the passage of a current.

On the Hughes' Electro-magnet, and some of its Applications.—M. Lartigue.—Will appear in a future number.

Experimental Determination of the Dielectricity Constants of some Gases.—M. L. Boltzmann.—The dielectric constant of vacuum is taken as unity. The square root of the constant of a gas is, according to Maxwell's theory, equal to the index of refraction of the gas. The following table gives M. Boltzmann's figures obtained from experiment, with a pressure of 760 m.m.:—

	$\sqrt{D}$.	i.
Air	1·000295	1·000294
Carbonic acid	1·000473	1·000449
Hydrogen	1·000132	1·000138
Oxide of carbon ..	1·000345	1·000340
Protoxide of nitrogen	1·000497	1·000503
Olefiant gas	1·000656	1·000678
Marsh gas	1·000472	1·000443

The dielectric constant of sulphur changes, conformably to Maxwell's theory, when taken in a different direction relatively to the optic axes of the crystal.

An Experiment on the Electro-Dynamic Action of the Polarising Current.—MM. Schiller and Colley.—The authors' object was to find whether a liquid conductor exerts electro-dynamic action while the electrodes in it are polarised. In a Wiedemann galvanometer, which has two movable wire-coils on the two sides of the magnet, one coil was removed, and a spirally wound caoutchouc tube substituted. In this were put distilled acidulated water and two platinum electrodes. A current of four Daniells, which, notwithstanding the great resistance, wrought considerable decomposition of the water, was sent in opposite directions through the liquid and the metallic spirals, and these were moved till they compensated each other in action on the magnet. Then one Daniell was substituted for the four Daniells. Neither at closing the circuit nor afterwards, on closing the wire, with the battery excluded, was the least movement observed in the magnet. Hence it follows that the process going on in the liquid is, in its action on the magnet, perfectly equivalent, both qualitatively and quantitatively, to the galvanic current passing in the metallic part of the circuit.

Electrical Length.

The term "electrical length" has been employed in contradistinction to the ordinary or physical term by which the idea of length is conveyed. Electrical length is of course synonymous with electrical resistance. In the laboratory, and even in our handbooks, the expression "a wire of so many ohms" is common, and it is necessary that the student should dissociate the idea of physical length from such an expression. To the electrician the expression "a wire of 10 ohms," or "10 ohms of wire," conveys as distinct meaning as "10 yards" or "10 miles" laid out by ordinary physical measurement. Given a definite electrical unit of resistance, it is always as easy to measure by electrical appliances the value of that resistance as it is to put a rule or tape by the side of a wire, and to say how long is the wire. A circuit, then, of ten ohms, electrical length does not necessarily include that it should be greater in physical length than one of five ohms, or just half the amount, because if the ten ohms' wire be a very thin wire only a short piece will interpose twice as much resistance as a mile of the five ohms' wire if the latter be very thick or coarse.

But in telegraphic or other work where one gauge of wire is principally employed, it is not unusual to speak of the actual length of the wire in terms of the resistance-coils. Thus, instead of saying that the line from London to Birmingham is so many miles in length, we may say it is so many ohms or units long, meaning that the line-wire between London and Birmingham has so many ohms or units of resistance, and our meaning is as clear and as true as if it had been expressly stated.

This idea of electrical length will bear great extension, and will be so extended during the discussion of electrical principles with our students. It is better, therefore, now to lay down clearly the difference between electrical and physical length.

Researches on Interrupted and Interverted Currents, and their Thermal and Electrodynamic Effects.—M. Villari.—An iron wire is heated more by an interrupted current than by a constant one, and still more, if the direction be reversed at each interruption. The *augmented resistance* increases (M. Villari finds) with the thickness of the wire; also with the intensity of the current, but only to a certain limit. It further increases with the rapidity of the interruptions and the number of reversals per second.

15

the action of the electro-magnet than when it is fixed, and naturally so, because the rotating disc remains too short a time with each of its diameters in the axial direction of the magnetising magnet to receive all the magnetism it is capable of receiving when allowed a longer time.

Professor Villari describes a series of researches springing out of those described. The general results obtained are thus summed up:—

1. The action of rapid rotation of a flint glass disc between the poles of an electro-magnet has the effect of lessening the magnetism produced in the disc.

2. This diminution is greater the more rapid the rotation.

3. In order to make a weak diamagnetism disappear, a less rapid rotation is required than to destroy a stronger.

4. In order to call forth such a diamagnetic intensity in flint glass as can be observed through the rotation of the plane of polarisation, a space of time not less than 0·001244" is necessary.

5. The time is not always the same, and it decreases with the increase of the magnetising force. Hence the diamagnetic motions in flint glass are the more rapid the greater the demagnetising force.

6. In order to produce in flint glass the whole diamagnetism which it is capable of receiving under the action of a strong electro-magnet, a time not less than 0·00241" is necessary, this being nearly three times as much as is required for the first symptoms of diamagnetism to show themselves.

7. The diamagnetism in flint glass, under the conditions of experiment described, continues for a space of time which is less than 18 hundred-thousandths of a second.

THE SELECTION AND NOMENCLATURE OF DYNAMICAL AND ELECTRICAL UNITS.*

We consider that the most urgent portion of the task entrusted to us is that which concerns the selection and nomenclature of units of force and energy; and under this head we are prepared to offer a definite recommendation.

A more extensive and difficult part of our duty is the selection and nomenclature of electrical and magnetic units. Under this head we are prepared with a definite recommendation as regards selection, but with only an interim recommendation as regards nomenclature.

Up to the present time it has been necessary for every person who wishes to specify a magnitude in what is called "absolute" measure, to mention the three fundamental units of mass, length, and time, which he has chosen as the basis of his system. This necessity will be obviated, if one definite selection of three fundamental units be made once for all, and accepted by the general consent of scientific men. We are strongly of opinion that such a selection ought at once to be made, and to be so made that there will be no subsequent necessity for amending it.

We think that, in the selection of each kind of derived unit, all arbitrary multiplications and divisions by powers of ten, or other factors, must be rigorously avoided, and the whole system of fundamental units of force, work, electro-static, and electro-magnetic elements, must be fixed at one common level—that level, namely, which is determined by direct derivation from the three fundamental units once for all selected.

The carrying out of this resolution involves the adoption of some units which are excessively large or excessively small in comparison with the magnitudes which occur in practice; but a remedy for this inconvenience is provided by a method of denoting decimal multiples and sub-multiples, which has already been extensively adopted, and which we desire to recommend for general use.

On the initial question of the particular units of mass, length, and time, to be recommended as the basis of the whole system, a protracted discussion has been carried on, the principal point discussed being the claims of the gramme, the *metre* and the second, as against the gramme, the *centimetre*, and the second; the former combination having an advantage as regards the simplicity of the name *metre*, while the latter combination has the advantage of making the unit of mass practically identical with the mass of unit volume of water; in other words, of making the value of the density of water practically equal to unity. We are now all but unanimous in regarding this latter element of simplicity as the more important of the two; and in support of this view we desire to quote the authority of Sir W. Thomson, who has for a long time insisted very strongly upon the necessity of employing units which conform to this condition.

We accordingly recommend the general adoption of the centimetre, the gramme, and the second, as the three fundamental units; and until such time as special names shall be appropriated to the units of electrical and magnetic magnitude hence derived, we recommend that they be distinguished from "absolute" units otherwise derived, by the letters "C. G. S." prefixed, these being the initial letters of the names of the three fundamental units.

Special names, if short and suitable, would, in the opinion of most of us, be better than the provisional designations "C. G. S. unit of . . . . . ." Several lists of names have already been suggested; and attentive consideration will be given to any further suggestions which we may receive from persons interested in electrical nomenclature.

The "ohm," as represented by the original standard coil, is approximately 10^9 C. G. S. units of resistance. The "volt" is approximately 10^8 C. G. S. units of electromotive force, and the "farad" is approximately $\frac{1}{10^9}$ of the C. G. S. unit of capacity.

For the expression of high decimal multiples and sub-multiples, we recommend the system introduced by Mr. G. J. Stoney—a system which has already been extensively employed for electrical purposes. It consists in denoting the exponent of the power of 10 which serves as multiplier, by an appended cardinal number if the exponent be positive, and by a prefixed ordinal number if the exponent be negative. Thus:—

10^9 grammes constitute a *gramme-nine*,

$\frac{1}{10^9}$ of a gramme constitutes a *ninth-gramme*,

Distribution of Magnetism in the Interior of Magnets.—MM. Trève and Durassier.—In this paper, which cannot be intelligibly abstracted without the accompanying diagrams, we find the interesting observation that those parts of a magnet where its force is greatest are less readily attacked by acids than its neutral or central parts.

We have pleasure in calling the attention of our readers to a course of fifty lectures, on Electricity and Magnetism, which are being delivered by Prof. Foster at the University College, and which are advertised in our first page.

Terrestrial Magnetism.

To the Editor of the Scientific American: Oct 75

In an article entitled "Terrestrial Magnetism" on page 161 of our current volume, I notice a statement which may mislead, and beg leave to correct it. "That the earth is not a great magnet, but that the phenomena of the magnetic needle are due to the electric earth currents which flow at right angles to the earth's axes." These two statements are contradictory. "The earth is a great magnet, and the phenomena of the magnetic needle," etc., is the way it ought to have been put. For all our most recent knowledge tends to confirm Ampère's theory that a magnet is merely a closed circuit of electric currents acting parallel and in same direction, and not necessarily a mass of iron, nickel, or cobalt. So that the earth, being surrounded by such currents, is as much a magnet as the magnetic needle. I. B. M.

Hoboken, N. J.

OCTOBER 23, 1875.

Electric Force and Molecular Motion.

To the Editor of the Scientific American:

Mr. W. E. Sawyer, in his letter on "What is the Electric Force?" in your issue of October 9, says: "When one pulls a bell cord, and instantaneously a bell is rung in a distant room by the molecular transmission over or through the bell wire of the force applied at the cord, does not one realize that he is as veritably, as wonderfully, and by a similar molecular motion, transmitting that signal as though he were transmitting it by applying a battery to a telegraph wire, and thus setting the atomic particles in motion?"

I propounded the above question to myself, endeavored to realize it, and failed signally; therefore I apply to you for help, and trust it will be given, for Mr. Sawyer's explanations of the electric force seem so clear and forcible as to enable almost any one to form a good idea of the subject.

When one pulls a bell rope, causing a bell to ring at a distant point, one can readily realize the disturbance of the atomic particles from ocular demonstration. He sees the movement of the cord where the force is applied, and also where the bell lever receives it, and the only rational explanation is that of molecular transmission.

In the case of the telegraph, he sees no motion, either where the force is applied, or where it is taken off, even when the force so applied is very powerful. However, this may be deduced by reasoning, as Mr. Sawyer so ably shown, but the real difficulty is at the end, where it is utilized. The wire terminates in a coil, and inside of this coil, entirely separated from it, is a bar of metal, and entirely separated from this is the bell lever. Now it is difficult to conceive how the mere molecular disturbance at the wire causes a like disturbance in the bar, which again causes the same in the bell lever or armature. If the motion were transmitted directly to the bell lever by a material connection, as in the first case, then there would be no difficulty in understanding this application of the theory.

On the Depth of the Magnetised Layer in a Steel Bar.—M. J. Jamin.—Having previously shown that magnetisation penetrates to a finite depth into steel, M. Jamin experimented upon the limit, and the law of the decrease of the intensity from the surface to that limit. It suffices to quote the experiment of the breaking of a magnet to affirm that a bar is composed of threads, or elementary chains, of small magnets, which succeed and join one another by their contrary poles. Granted that these threads are all equal to one another,—that is to say, they are grouped in bundles of the same strength,—he assumes that in their whole length the contrary poles which are in juxtaposition are entirely concealed, in such a manner that the threads are inactive excepting at each extremity, where a single free pole is found. Being inactive, they extend parallelly to the axis in the prismatic bars, as far as the extremities; but, as there are there free poles which repulse each other, they expand by diverging, and terminate at the various points of the free surface, where they develope reactions. Upon each superficial element the intensity is proportional to the number of poles found there, and to the square of the force with which its attraction is overcome. The total number of the threads, or the total quantity of magnetism, is equal to the sum of the intensities on each element,—that is to say, the sum of the square roots of the detaching forces. M. Jamin quotes four points which he set himself to examine:—(1) the sum total of the threads which cross the middle zone of the magnet; (2) the law of distribution in this zone; (3) the sum total of the intensities distributed over the free surfaces; (4) the distribution of these intensities. Four series of steel plates were prepared with thicknesses of 1, 2, 3, 4 millimetres, and each 1 metre long by 50 m.m. broad. After saturating them with magnetism by means of a powerful coil, the magnetism developed on their surfaces was measured. First, the plates were divided into five bands by four equidistant lines running parallel to their length; then on each line, at certain distances, the detaching forces of a small trial contact-piece, suspended to the scales of a balance, were measured. The square roots of these forces represent, at each point touched, the magnetic intensity. The mean of five drawn curves, representing the intensities as measured, was taken, and the author stated—"It is clear that the *area* of this curve measures the whole of the magnetism, or the number of elementary threads, contained in a longitudinal slice of the magnet perpendicular to its thickness." The results of his calculations to discover this area led him to conclude that the magnetic threads *are less numerous* in proportion as one removes from the perimeter of the middle zone, and in proportion as one penetrates into the substance. That was evident *a priori*, but the author argues further that during magnetisation the force of the coil exerts itself directly upon the surface; but, experiment proving that it is not transmitted through a bed of steel of sufficient thickness, we can but admit that its action on a core rapidly diminishes with the depth. Call F the intensity in the exterior points: it will be $\frac{F}{a}$ at a distance 1, $\frac{F}{a^2}$ at a distance 2, and $\frac{F}{a^y}$ at a depth *y*. Now the quantity of magnetism developed in a slice whose thickness is dy

On Magnetic Bundles Formed by Plates Separated by Intervals.—By M. J. Jamin.—Continuing his study respecting magnetised bundles, contented himself with measuring their magnetic moment. He found that this moment increases less rapidly than the number of plates. The problem was badly put, for it was to measure the force of a bundle by the product of two factors—the totality of the magnetism and the distance of the pole from the centre. Now these two factors vary at once and in opposite direction. It was far simpler to seek the law which governs one only of these two factors, and it was that which led M. Jamin to estimate the total magnetism, and to prove that in a bundle it is rigorously equal to the sum of the magnetism of the elements. He now demonstrates how the laws of bundles modify themselves without ceasing to be very simple, when the plates, instead of being rigorously attached and close to one another, are par[illegible]

[20030.]—Electrical Strength.—I am afraid that this will be rather a difficult thing to answer, but I am of opinion that a person in good health cannot take so much as a person in bad health. I have seen a little girl about six years old taking more than three grown up persons could bear.—Tele. Lineman.

[20030.]—Electrical Strength.—From reading the replies given in last Saturday's number, I am tempted to contribute my item of explanation. How very few people understand the expression so frequently used about having strong nerves or the reverse. First of all, the "strength" does not lie in the nerves at all, but is merely an impression or influence resident in the brain or other nerve-centres, and on occasion it stimulates the nerves and thereby excites the contraction of the muscles. Now the action of a current of electricity does the same thing—it excites a powerful contraction of the muscles, independently of the brain or of the nerves, except that the latter act as conductors, as may be seen in a frog, by making the legs twitch after the remainder of the body has been removed, and it must be noted that it (the strength) depends more on the power of will (the influence referred to) conveyed by the nerves than absolutely on the size of muscles, and a weak person under the influence of powerful excitement, has performed feats which a much stronger person without the impulse would fail to achieve. A phrenologist would probably say that the strength would depend on the development of the bump of endurance (I forget the scientific cognomen), as any one by a preformed determination can sustain a much more severe shock than he could generally. To make a fair test of relative endurance of the electric current the hand must be soaked in water slightly salt before seizing the conductor, as it does away with the resistance of the epidermis.—Alfred.

Distribution of Magnetism in a Thin Plate of Great Length.—M. J. Jamin.—The author has been engaged in studying the distribution of magnetism in a bundle of rods, commencing with the most simple case, that of a single broad plate, so long that it may be regarded as infinite, and of an equal thickness of 1 millimetre. He has experimented upon various pieces taken from a long and very homogeneous band of steel.

— Les *Mondes* publient une correspondance du R. P. Lafond, sur l'*Observatoire météorologique et magnétique* établi à Zi-Ka-Wei (Chine).

Notre observatoire, dit-il, est dans ses commencements, puisque les observations magnétiques ne datent que de deux ans; nous construisons en ce moment la salle qui doit contenir le grand appareil enregistrant par la photographie les variations des éléments du magnétisme terrestre tel qu'il est installé et qu'il fonctionne régulièrement à Kiew depuis longtemps : ces phénomènes magnétiques sont ici d'une régularité surprenante; aussi j'ai tout lieu d'espérer de notre appareil une ample moisson de faits pour l'étude de ces phénomènes intéressants.

June 76

[illegible] on rotatory magnetic Polarisation.—M. H. Becquerel.—It results from these researches that the molecules of bodies submitted to the action of magnetism interfere by their specific action with the phenomenon of the rotation of the plane of polarisation of light, and that for highly magnetic bodies this action varies with the mutual distance of the active molecules.

MANCHESTER

Literary and Philosophical Society, Nov. 2.—Mr. R. Angus Smith, F.R.S., vice-president, in the chair.—Mr. Peter Spence, F.C.S., &c., exhibited a piece of 2 to 3-inch lead pipe in which the metal had been entirely transformed into galena, the crystallisation being visible through the whole of the specimen. The pipe had been used for the conveyance of gas ammoniacal water, and was sunk under ground. A considerable leak of gas-water having occurred, a constant atmosphere of sulphide of ammonium would surround the pipe, and this seems to have been the cause of the conversion of the lead into sulphide, as only that part of the pipe which was in the vicinity of the leak was found to be transformed.—On the principle of the electro-magnet constructed by Mr. John Faulkner, by Prof. Osborne Reynolds. The magnet which forms the subject of this paper consists of a soft iron bar with a flat plate attached to one end, and surrounded by a coil of wire in the same way as the ordinary electro-magnet. Outside this coil is placed a tube of soft iron of the same length as that portion of the interior bar which projects beyond the plate; this tube has flat ends, one of which is in contact with the plate, while the other comes up flush with the end of the bar, so that a plate or keep placed over the end is in contact with both the bar and the cylinder. The magnet is excited in the ordinary way, by connecting the ends of the wire which forms the coil with the poles of a battery. When thus excited this magnet exhibits certain peculiarities as compared with a common magnet. The object of the paper was to suggest explanations of these phenomena.

[23811.]—Potential.—To "Sigma."—"Beacon Lough" appears to be in the muddle which is the very common result of the use of the Shibboleth "potential." The word has so many meanings given to it and is so constantly used improperly that such confusion is inevitable. Because I have objected in my book to the constant use of the word where it is not truly applicable, the reviewer, in *Nature* is good enough to say I do not understand the term. This may be the case, as I have never yet met two people who could give the same definition of potential, and it is quite impossible to get any intelligible explanation from the various electrical books, which all use without explaining it, or give definitions entirely inconsistent with each other. It is, to begin with, unmeaning to speak of "potential" at all, or to talk of two bodies being at the same potential: potential has no existence, the term has meaning only when used in the form of *difference of potential*. Potential is relative only, and the use of the term in the form which "B. L." adopts (and as nearly every one does, in fact) tends only to confusion and delusion, just as does the equally common and equally absurd term "putting to earth." The earth has nothing to do with a charged condenser, except that, in making the so-called "earth connection," a derived inductive circuit may be set up, withdrawing part of the charge from the condenser. The two plates form mere surface connections to the really charged body, the di-electric; you may connect either one of the plates singly to "earth" or to the universe at large, or even to a body in a condition of vehement + or − charge, and you will produce no effect whatever upon the condenser (ignoring, that is, the question of derivation). Therefore to talk about the earth and this plate being at the *same potential* is merely to construct a wholly useless mathematical "bogy," which produces alarm and confusion in those who do not see that it is a pure imposture. Mathematicians choose to say they are at the same potential *because* no current passes, and because they have defined potential as the cause of current or electric action; but the simple fact is that there is no relation whatever, and the expression is a mere empty symbol for that fact. It is just the same when the second plate is separately connected; there is again no relation to earth, but there is a discharge of the derived inductive circuit set up at first in some cases. Relations of potential can exist only where there exist relations of circuit, and in the case put there exist only in the di-electrics—1, The material of the condenser; 2, The air between the condenser and the surrounding objects. If connection has been made to these, or to "earth" according to the commonly taught fables. In electricity "earth" means simply zero or a common conductor; the actual globe or earth has no part to play in our operations except when we use it as a large wire of scarcely appreciable resistance.—Sigma.

Vol. II.—No. 31.

PRELIMINARY EXPERIMENTS ON A MAGNETISED COPPER WIRE.*

By Prof. BALFOUR STEWART, M.A., LL.D., F.R.S., and ARTHUR SCHUSTER, Ph.D.

1. The following experiments were made in the Physical Laboratory of Owens College, Manchester. The copper wire employed was found to contain no perceptible trace of iron, nor was it sensibly magnetic, behaving quite in a neutral manner when tested by the highest magnetic power at our disposal. It was covered with gutta-percha. The diameter of the wire was 0·0487 inch. The wire was wound fifty-three times in one direction round the poles of a powerful electro-magnet, the length of wire encircling these poles being about 12 metres. The direct distance of the magnet from the galvanometer was about 12 metres.

A Wheatstone bridge was employed, and a very delicate Thomson's reflecting galvanometer by Elliott Brothers, of which the resistance was 5540 B.-A. units. A circuit-breaker was placed in the circuit close to the bridge. On some occasions we used one consisting of a solid key which might be removed, thus breaking the circuit; but on other occasions a fluid or mercurial circuit-breaker was employed.

When the left-hand pole of the electro-magnet was made north the arrangement was called (1), and when the other pole was made north the arrangement was called (2). It will thus be seen that the current went round the magnet in the same direction as the molecular currents of arrangement (2).

Experiments were made at intervals of two minutes; and on each occasion the current was allowed to pass through the bridge for ten seconds, the measurement being taken by the first swing of the galvanometer, which lasted for about eight seconds. Three cells of Grove's battery were used for producing this current, but on the other hand six similar cells were employed for magnetising the electro-magnet. The distance of the magnet was too great to affect the galvanometer-needle so as to alter its sensibility, the average deflection causing a difference in the zero of about four divisions of the scale.

2. In the first experiments made the key was not taken out before the magnetism was put on or off, in consequence of which the induction-current due to the wire coiled round the magnet affected the galvanometer on these occasions; but after December 12th the key was taken out, so that no induction-current passed.

The table at top of next column is a specimen of the observations made.

It will be seen from this experiment that the *first effect* of putting on the magnetism was a marked increase of resistance; but with this exception the

41	292	(1)
43	309	off

resistance, when the magnetism was on, was less than the mean of the two resistances on both sides of it, representing the magnetism off.

3. The arrangement remained untouched, as far as we know, from December 15th, when it was finally made, until December 19th, when the experiments were interrupted during the Christmas holidays; and in all cases the *first effect* of putting on the magnetism was a marked increase of resistance. For instance, we have—

Date.	First Off.	First Effect.	Second Off.
Dec. 16 ...	0	+36 on (2)	+ 3
„ 17 ...	0	+34 on (1)	+17
„ 18 ...	0	+54 on (1)	+24
„ 19 ...	0	+33 on (1)	−18

It was soon seen that this *first effect* had some reference to the time elapsing since the last experiments were made. For instance, in the above table we see for December 18th a marked increase of resistance when the magnet was first put on; but on the afternoon of that day the experiments were repeated, and there was no apparent increase of resistance in this *first effect*. Next, with regard to the *average effect* on Dec. 16th, 17th, and 18th, this *average effect* of magnetism was a decrease of resistance; but on Dec. 19th there was an apparent increase of resistance when the magnetism was on. We cannot say that nothing had been done to the arrangement between the 18th and 19th of December that might account for this change, but whatever was done must have escaped our recollection. Undoubtedly a good many experiments were made during the time between the 15th and 19th of December, and the direction of the magnetism was frequently changed. This curious anomaly occurring unexpectedly induced us to limit our future experiments to a definite set each day.

4. The experiments were resumed on January 7th, the arrangement having remained untouched during the holidays. From this date until January 10th inclusive the key was taken out before beginning experiments in the morning; there was no peculiar *first effect*; while, on the other hand, an *average effect*, denoting a decrease of resistance, came out very prominently. On January 12th and 13th the key was only taken out before magnetising, and on those occasions the *first effect* denoting increased resistance was sufficiently marked.

to address such an audience, either with the pen or the voice, and gave as an illustration a great meeting convened by his fellow-citizens to welcome him back to Canada after he had been knighted. He was, of course, expected to say something of himself and of his visit to Europe. He tried his best, he said, but soon grasping a long pointer, turned round to some maps and diagrams illustrative of the geology of Canada, and only recovered his peace of mind and command of language when he found himself once more among Laurentian, Huronian, gneiss, limestone, and the rest of his beloved rocks. Nevertheless, he kept copious journals of his various expeditions, and illustrated them with most admirable pen-and-ink sketches. A selection from these could hardly fail to be of great interest, both in relation to the man himself and to the way in which geology has to be carried on amid the wild life of the backwoods.

By those who were privileged with his friendship, Sir William Logan will be affectionately remembered as a frank, earnest, simple-hearted man, ever gentle and helpful, enthusiastically devoted to his profession, and never happier than when discussing geological questions in a *tête-à-tête*, full of quiet humour, too, and showing by many a playful sally in the midst of his more serious talk, the geniality and brightness of his sunny nature. Peace to his memory! He has done a great work in his time, and has left a name and an example to be cherished among the honoured possessions of geology.

ARCH. GEIKIE

TREVANDRUM MAGNETIC OBSERVATIONS

Observations of Magnetic Declination made at Trevandrum and Agustia Malley in the Observatories of his Highness the Maharajah of Travancore, G.C.S.I., in the Years 1852 to 1869. Vol. i. Discussed and edited by John Allan Broun, F.R.S., late Director of the Observatories. (London: Henry S. King and Co.)

WE have heard a great deal lately about the native rulers of India, and the worst features of one of them have been brought very prominently before us; but it is a pleasing reflection that they are not all like the potentate of Baroda, while some of them might even read a lesson to the paramount power. Let us hear what Mr. J. Allan Broun, a magnetician of great eminence, has to say of the late ruler of Travancore.

"The Trevandrum Observatory," he tells us, "owed its origin in 1836 to the enlightened views of his Highness Rama Vurmah, the reigning Rajah of Travancore, and to the encouragement given to them by the late General Stuart Fraser, then representing the British Government at Trevandrum. His Highness, desirous that his country should partake with European nations in scientific investigations, sanctioned the construction of an observatory, named Mr. Caldecott its director, and gave him power to furnish it with the best instruments to be obtained in Europe."

The peculiar position of Trevandrum, not far from the magnetic equator, induced Mr. Caldecott, with the Rajah's permission, to procure from Europe a complete equipment of the best instruments for magnetic and meteorological observations, and to build a magnetic observatory, which was completed in 1841.

Mr. Caldecott died at Trevandrum in 1849, and the observatory was in January 1852 placed under the direction of Mr. John Allan Broun, who had previously directed with well-known success the observatory of Sir T. Brisbane at Makerstoun, in Scotland.

Mr. Broun began his office with the conception of an interesting and important problem in terrestrial magnetism, which he was determined as far as possible to work out. This would render it necessary that the observations should not be limited to a single station. He wished, among other things, to determine how far the physical constants of terrestrial magnetism and their various changes depend on differences of height, of latitude, and of longitude.

The Agustia Malley, the highest mountain in the neighbourhood, was chosen as affording the best means for determining the effect of height, and accordingly Mr. Broun resolved to erect an affiliated observatory on this nearly inaccessible rocky peak, surrounded by forests, the inhabitants of which were elephants and tigers. These and all other difficulties connected with this formidable undertaking were, however, completely vanquished, and the Agustia Observatory was completed in 1855.

We learn from Mr. Broun that his labours were not entirely confined to these two observatories. "Other observations," he tells us, especially of magnetic declination, were made simultaneously "during short periods at different stations in Travancore, as nearly as possible on the magnetic equator, 90 miles north of Trevandrum, and also 40 miles to the south. Observations connected with meteorological questions were also made simultaneously to the east and west, and about 5,000 feet below the Agustia peak, on the peak itself, and at Trevandrum; while on one occasion hourly observations were made during a month at five different stations, varying gradually in height from the Trevandrum Observatory (200 feet) to 6,200 feet above the sea-level, in which fifteen observers were employed."

In this first volume Mr. Broun has confined himself to the magnetic declination, and one of the chief objects sought has been to determine every possible action of the sun and moon upon the magnetic needle. The observations extend from 1852 to 1870, and embrace in all nearly *three hundred and forty thousand readings.*

A considerable portion of the introduction is devoted to the discussion of a question which has, we think, been somewhat too much overlooked. When a magnet is suspended by a thread and enclosed in an appropriate box, it does not necessarily follow that all its movements are due to magnetic causes, for changes in temperature and humidity may affect the zero of torsion of the thread, and thus cause slight changes in the position of the suspended magnet. It is perhaps unlikely that such changes could seriously affect the character of the daily variation, but it has been thought that they might perceptibly affect the annual variation, since in this case the magnetic change is comparatively small, while the range of temperature and humidity is generally great.

Mr. Broun overcame this source of error by observations of an unmagnetic brass bar suspended in the same way as the magnet, which thus afforded him the means of estimating, and hence eliminating, the error due to these causes.

Besides all this, several declinometers were used and to discuss those by themselves, and the result has been the most interesting and important discovery of the law of storms. And if it be asked what right meteorologists had to separate a body of disturbed observations, the reply will obviously be that they are justified by their success. Deny the right, and a cyclone becomes an altogether false and illegitimate scientific conception.

Now, a large and increasing number of magneticians are of opinion that the phenomena of terrestrial magnetism can bear a similar treatment. They believe that the sun has a daily and yearly influence on the magnetism of the earth just as it has upon its meteorology, and they also believe that it is the cause—the indirect cause, it may be—of an abnormal magnetic influence, just as in meteorology it is the indirect cause of the cyclone. Some even go so far as to say that these two abnormal influences, the one in magnetism, the other in meteorology, are intimately connected together. This assertion, however, is not now the point in question. The point is that we have in magnetism certain abnormal disturbances which may be compared to abnormal meteorological disturbances. Now, it is held by Sir E. Sabine and those who share his views, that it is expedient to separate out these disturbed magnetical observations, just as we separate out the meteorology of a cyclone. This school assert that we may thus arrive at a series of phenomena obeying very different laws from those of the undisturbed observations, and that we are therefore justified in making the separation, inasmuch as we are thereby led to a clearer knowledge of the various ways in which the sun affects the magnetism of the earth. And they insist very strongly upon the point that both these magnetic actions of the sun have diurnal and annual variations different from one another, so that if treated together we obtain a result much more complex than if they be treated separately.

We have little doubt of the policy of this method of treatment, and we cannot, therefore, but regard it as a misfortune that Mr. Broun has not unmistakably adopted it. He has, however, given us all the individual observations, so that, if it be thought desirable, those magneticians who advocate a somewhat different method of reduction may make it for themselves. We need only add, in conclusion, that the appendices will be found to be very interesting reading, and that all who are interested in terrestrial physics must look with great interest to that magnificent series of researches of which the volume before us forms the first instalment.

B. STEWART

Faraday's experiment is well known, which consists in placing between the poles of a strong electro-magnet a cube of copper or silver suspended at the end of a twisted cord: the cube being left to itself quickly rotates; then a current is sent into the electro-magnet, and the cube is instantly arrested. Foucault produced a similar effect on a rotating copper disc. A pretty way of exhibiting this effect to an audience has been described by M. Bourbouze to the French Academy. He fixes the copper disc to the axis of the moving plate of a syren. A blast of air being sent into the syren produces the rotation, with gradually rising sound. On making the electro-magnet the disc stops, and the sound is suddenly extinguished.

21

DISTRIBUTION OF MAGNETISM IN BUNDLES OF VERY THIN PLATES OF FINITE LENGTH.

{ELECTRICAL NEWS, August 26, 1875.

By JULES JAMIN.

MY previous researches have had for their object the determination of, first the "Distribution of Magnetism in a Thin Plate of Great or Infinite Length,"* and then the distribution in a bundle composed of several such plates.† I now propose to study the general case in which the bundle has a *finite* length *l*.

air take place freely through the extremity of the section. At the instant when the carrier clears the space separating arrival line from the departure line, he closes behind it the departure line, and opens a stop-cock communicating with the reservoir of compressed air, which drives it through the following section of the line. He also keeps the cock open until communicated with by the operator at the next station.

Such an apparatus, we are informed, worked regularly for some months in France. The escapement of air took place in front of the relay, through a piece of tube perforated in every direction, and affording a passage equal to twice the section of the line. The closure of the line behind the carrier, and communication with the compressed air, was effected by a sort of trigger upon which the carrier acted as soon as it cleared the relay. The period of "blowing" was measured with a piston raised in a cylinder by means of the inner pressure; the law of this ascension being regulated by counter pressure in such a manner that the "blowing" lasted as long as the desired time. Directly the carrier reached its destination or entered into the continuing section, the pressure in the line fell, and the piston dropped.

The objection to the apparatus was its susceptibility. It encloses a delicate valve to close the line, and if a foreign body even partially opposes its working, the relay becomes itself an obstacle to the efficiency of the line.

To remedy this state of things it was necessary to suppress the valve, which, after the description just given, appeared to be the chief piece of the instrument. It could not be suppressed unless the escapement were suppressed; and the escapement could only be abolished at the expense of the counter pressure. This series of observations led to a project which has completely solved the question. The line is of double effect; by means of special apparatus which are really relays, it is constantly maintained empty of air, and consequently, the more compression, the more valves in the pressure relays.

The line, which we will suppose of illimited length, is escorted by two secondary pipes uniting with the suction and pressure reservoirs designed to supply the relays placed at convenient spots on the line.

These relays are of two kinds. Those whose object is to empty the line of air are placed at distances of 5 kilometres in those cases where the line will be traversed by carriers spaced by a quarter of an hour's interval. They are, moreover, extremely simple: a piston rising in a cylinder carries with it a valve closing the line and a slide opening the exhausting reservoirs. The piston is raised on the passage of a carrier by the action of the counter-pressure which follows it; it closes the line behind it, and immediately begins the exhaustion of the section just traversed. The valve borne by this relay is not subject to any of the inconveniences met with in those first invented.

The pressure relays are distant from each other 1 kilometre, and are simple "blowers," being opened on the carrier's passage, and blowing all the time the carrier is in their sections. They are merely formed of a piston carrying a counterpoise acting against a slide. The air enters the line through a kind of lantern (*lanterne*) studded with holes having twice the section of the line; and notice for blowing is given by the carrier itself, which, striking a detent, causes a counterpoise placed upon the piston and commanding the slide to fall. The blowing is instantaneous. It is suspended by the regulating piston's action, which closes the communication to line, and confines compressed air in a small chamber placed between this closer and slide. The effect of this compressed air at the moment when the pressure is lost in the line, *i.e.*, when the carrier has cleared the section, is to lift up the piston acting upon the slide and to put it in position for the arrival of the next carrier. This apparatus, which is the soul of the new system, is extremely simple and needs no supervision. It is accompanied by a reservoir of compressed air sufficient to serve its section.

There now remains but to examine the speed of a line furnished with these relay instruments. Let the line be 100 m.m. diameter, the suction-pressure be 50 centimetres of mercury, and the driving pressure be 76 centimetres of mercury. The comparison will be made between a line as above and the Parisian net-work, where a pressure of 40 centimetres of mercury gives a speed of 20 metres a second in a line 1000 metres long and 65 m.m. diameter. The increase in diameter will augment the speed thus:—

$$\sqrt{\frac{100}{65}}\times 20 = 25 \text{ metres per second.}$$

The consideration that the line is constantly empty of air will reduce the friction-length of the sections of 1000 metres to a mean of 600 metres maximum; for, on entering each of the sections, *i.e.*, at the moment when the train clears the pressure relay, no column of air follows it, only at the end the column of air attains a length of 1000 metres. If exhaustion were absolute, the mean length of the friction column would be 500 metres. This diminution of the friction column gives a further increase of speed in the proportion of—

$$\sqrt{\frac{1000}{600}}\times 25 = \frac{33}{24}\times 25 = 34\frac{9}{24} \text{ metres per second.}$$

In addition to this, there is the augmentation resulting from the difference of pressures, which is likewise as the proportion of the roots—

$$\sqrt{\frac{76\times 50}{40}}\times 31\frac{9}{24} = \frac{115}{65}\times 34\frac{9}{24} = 61 \text{ metres per second.}$$

This speed is enormous, and probably might create inconveniences. The observation of trains proceeding under analogous conditions, with speeds of 40 to 50 metres, has shown that these speeds are practically quite admissible in regular working. It is only necessary to have a material extremely solid, and so arranged as to wear itself out without wearing out the line; this has been provided for by furnishing the rubbing parts of the carriers with a much softer metal than that of the line.

Pneumatic relay lines will certainly eventually become valuable communicating engines for correspondences at distant spots. The facility with which trains or carriers may be multiplied on lines without considerable expenses, the rapidity with which they are capable of progressing, will render them grand systems if applied to the postal service, for their speed of translation is triple that of the most rapid locomotive, if stoppages on railways are taken into account.

Scientif. Am. Aug. 29 1874

Scientif. Am. Aug. 29 1874

Magnets.

M. Jamin describes experiments which support these three propositions: (1) The number of elementary magnetic threads, and so the quantity of magnetism a magnet may contain, depend only on the middle section. (2) The opening (*épanouissement*) of the poles of these threads, or the distribution of intensities, is regulated by the form and extent of the exterior surfaces of the magnet. (3) If the surfaces diminish, the tension increases till they become insufficient to allow of the elementary poles opening out, and a portion of the two contrary magnetisms disappears, reproducing the neutral state.

On combining 22 magnetized plates (each 0 01 inch long, 0 04 inch thick, and 2 inches broad) in a bundle, with pasteboard 0 032 inch thick between adjacent plates, each plate lost magnetism, and so the bundle, the loss of the latter being 50 per cent, which is less than in the case (first experiment) of superposition without intervals; the loss was then 66 per cent. In this first mode all the magnetism retained was carried to the exterior; there was none, or almost none, between the plates. In the other mode the quantity remaining (161·1) was divided into two portions:—(1), 85·5, which was expanded on the exterior; and (2), 65·6, which remained in the intervals. With wider intervals the exterior magnetism diminished, the interior increased, and gradually the plates act as if they were independent.

SOCIETE D'ENCOURAGEMENT POUR L'INDUSTRIE NATIONALE.

At a meeting of the Council of Administration of this Society, under the presidency of M. Dumas, a letter from Sir Charles Wheatstone was read, who said, ... the coefficient of magnetic induction. This coefficient in the four above mentioned substances cannot be very different from air, which is taken as = 1. So that we have the index of refraction equal to the square root of the constant of dielectricity. M. Boltzmann accordingly compares the square roots of these constants as found by his method with the refractive indices as determined by Wollaston's method; and the differences may be attributed to errors of observation. He considers these results, though not so accurate as to lead to the identification of light and electricity, furnish strong support to Maxwell's theory.

nomena the term *meta-electrolytic* ... researches on the absorption of hydrogen by palladium, the author has made known—1. The quantity of heat (about 9000 calories) due to the formation of the alloy of hydrogenium and palladium; 2. That the condensation of hydrogen by palladium, and the condensation of gas by carbon are not in the least compatible. The method of condensation of hydrogen by platinum-black differs from that of hydrogen by palladium in plates. When the gas is introduced in successive portions into contact with the platinum-black until saturation is attained, the heat developed is not constant for the weight of gas absorbed, as takes place with palladium. Hydrogen indeed appears to form a true alloy with palladium, whilst with platinum-black it seems to form only layers of less and less density as it enters the metal. The action of platinum-black upon hydrogen appears to fall under the head of capillary affinity. The author repeats that he has been led to the conclusion that *oxygen* is not an immediate product of alco...

What is the Electric Force?

To the Editor of the Scientific American:

In continuing the explanation of my views on this subject, commenced by me on page 106 of your current volume, allow me to say:

In the point of sound force, we have accurately determined the number of vibrations of matter per second necessary to the production of a certain sound; in that of light force we have approximately estimated the number of vibrations, waves, or molecular motions per second necessary to the production of the various colors. In the point of heat force we have determined that it exists in a certain violent molecular motion; and in the point of electric force, we have determined that it also exists in a certain molecular motion. And I may here mention, as being one of the strongest proofs, the fact that a current transmitted through a bar of iron will not disturb it, the fact that a current transmitted around it will not disturb it, and the fact that a current transmitted simultaneously through it and around it will cause it to twist in a very appreciable degree, which would not be the case unless the electric force consisted of molecular motion. If we were in possession of no other proof that the idea of a fluid flowing through an electric wire is a myth, we might easily be assured of it by the fact that molecular motion alone is the necessary condition of all other forces. This motion, beyond doubt, varies in intensity and form in different forces, but that it is the one condition of force there can be no doubt: and that the only difference between the forces is the difference between molecular actions may be accepted as a truism. To my mind the force of attraction of gravitation, and perhaps the more remarkable orbital motions of the planets, are forces to which the electric force bears no comparison. The electric force, in fact, is no more mysterious than is any other force. When one pulls a bell cord, and instantaneously a bell is rung in a distant room by the molecular transmission over or through the bell wire of the force applied at the cord, does not one realize that he is as veritably, as wonderfully, and by a similar molecular motion, transmitting that signal as though he were transmitting it by applying a battery to a telegraph wire and thus setting the atomic particles in motion? Cannot one realize that, if there are bells at different places upon a long wire, the nearest bell will ring first and the most distant last? But no one would speak of a subtle fluid as the cause of the ringing, although there is just as much subtle fluid passing over the bell wire as there is when a telegraph operator in New York makes a signal in Chicago by applying the battery to the line of wire connecting the two distant places.

As in this force, so in electricity, nothing flows through the wire. There is, in fact, the most striking analogy between the molecular transmission of electricity and the molecular transmission of all other forces. The stronger and more rigid the lever, the larger and firmer the belt, the larger the tube for water or air, the better the transmission of the forces applied. The larger the conducting wire, the more perfect the transmission of the electric force: because the larger conductor we have, the more perfect must be the molecular motion.

We are now brought to consideration of one of the most important facts bearing upon the question of molecular motion and the theory of a subtle fluid. The force of the electric current is as the square of the distance or length of the

Scientific American.

conductor. A battery is a constant generator of electric force. These are our premises, and it is not difficult to understand that if, as according to the subtle fluid theory, a wire have a certain capacity to hold that fluid, just as a tube has a certain capacity to hold a liquid, it cannot matter what the length of the wire may be. It is well known, also, that the resistance of a wire varies as the square of the diametric amount of metal. Therefore, in considering the electric force as a fluid, we are bound to consider the wire as a reservoir for that fluid. Now an immense quantity of electricity passes over a very small wire in a certain period of time; and a wire ½ of an inch in diameter, the battery being of proper dimensions, will charge a condenser up to a certain point in one half the time that a wire of less diameter, composed of ½ the diametric amount of metal will charge it, and in one fourth the time that a wire composed of one fourth the diametric amount of metal will charge it; but the smallest wire will charge it to its full capacity as well as the longest wire, merely requiring more time in proportion. Therefore, if a battery be attached to a wire 100 miles in length, the subtle fluid theory would, as soon as the battery should have sufficiently charged the wire, make it necessary that the strength of the electric force in the 100 miles of wire should be as great as though the wire were but a mile, or a few feet, even, in length. This statement cannot be controverted.

Very far from this, however, is the case. We may have our battery upon the wire for any length of time, and we shall find that the force of the electric current still varies as the square of the length of the wire. This, alone, utterly disproves the theory that, in transmitting a signal by telegraph, the wire is charged by a subtle fluid, and proves beyond doubt that the action of the battery is to impart a certain force to the atomic particles of the conductor, which act, each in turn, upon the next and the next, losing force in each successive action, just as we behold every day in the operation of all the forces surrounding us, as, for instance, the ripples occasioned by the dropping of a pebble into a still pond, widening and widening and decreasing in force and intensity as the square of the distance. In the molecular action, there must be a loss of force every time one atomic particle imparts the electric force to another. This we know is the case. According to the subtle fluid theory, this could not be the case.

Again, if we can prove, as in the case of light, that one transparent substance will transmit certain rays of light and not others, we prove that the transmission of the light force is due to molecular action, that the light force itself, in fact, is a certain molecular action. This will be conceded; and I suppose I need not at this point endeavor to prove that such is the case, as the facts have been set forth by students in this line of science, among them Professor Tyndall, in far weightier terms than I am able to command. The one and only deduction to be made from the results attained is that certain atomic conditions are necessary to the transmission of certain forces, and that certain substances are incapable of assuming the atomic conditions necessary to the transmission of certain forces. The same general law holds good in respect of the electric force.

Without entering into all details of the subject, it may be asserted that the very fact that one metal is a better conductor of electricity than another proves conclusively that the propagation of the electric force is dependent upon the atomic structure of the metals; that as its propagation is dependent upon this atomic structure, the propagation of the electric force is by the atomic or molecular action of the metals; and that as this is true, so the electric force is a certain molecular action. The conductivity of the metals is expressed by their resistance, the metal offering the least resistance to the propagation of the electric force being the best conductor. Thus with the resistance of silver expressed as 107,

the resistance of quicksilver is 5,550, the latter metal, which is almost without tenuity of the atomic particles, being the poorer conductor, as would inevitably be the case under the molecular theory, and so would not be the case upon any other hypothesis. There are other causes, however, for the difference in the conductivity of different metals. Heat, we know, is a violent molecular motion. The electric force, being or consisting of a certain molecular action, should therefore be disturbed by the molecular action which constitutes heat; and we find that the resistance of a metal to the propagation of the electric force is increased by increase of temperature in the metal. The violence of the molecular action which is the electric force must be apparent to any one who witnesses the wonderful deflagrating effects of that force. Intense, we know, is the molecular action which constitutes heat; and it is a remarkable fact, as pointed out by Forbes, that the order of the metals as regards their conductivity for heat is the same as their order in conductivity of the electric force.

I will conclude the present article with one more argument in proof of the assertion that electricity is nothing more nor less than a certain condition of the atomic particles of matter.

The majority of the readers of the SCIENTIFIC AMERICAN have doubtless witnessed the discharge of electricity from a condenser, such as a Leyden jar, or from a battery or induction coil. They have beheld the brilliant sparks, and very many are cognizant of the fact that every spark is a particle of the metal of the discharging point heated to the state accessory to the production of the light witnessed. The electric light is not something which has passed over or through the wire, or something partaking of the nature of many metals which may compose the wire, but it is confined in kind to the properties of the metal composing the discharging point. Thus of platinum, silver, iron, copper, of which the discharging points may be composed, each gives its own peculiar light, no matter of what metal the greater length of the conducting wire may be composed: as, for instance, we may transmit the electric force through a hundred miles of copper or iron wire, and finally, when we get the discharge, it passes through a film of platinum $\frac{1}{1000}$ of an inch in thickness: but we get the same result in the kind of light produced as though the whole of the wire were platinum. Yet the electric force is the same no matter of what the conductor may be composed; and no reasoning can account for the projection of a flaming atom of matter from the discharging points, oftentimes with force sufficient to penetrate a piece of glass several inches in thickness, beyond the theory of intense molecular action.

The simple fact that the electric light which we witness is composed of the atomic particles of the conductor, heated to the state in which we observe them, and projected or following from the mass of the conductor, from one electrode to another (atomic particles which we know never have passed through the conducting wire, but have existed at and are wearing off from the terminal alone), proves beyond doubt that nothing that we witness in electrical phenomena has passed over the conducting wire in the sense of a current; that as this force is manifested at the distant end of the conductor in the shape of projected atomic particles of matter, it is clear that the electric force is a certain intensely active condition of the molecules of matter, which activity is set up by the violent action of acids upon metals or chemicals, by heat, or by friction, and transferred from one atom to another with inconceivable rapidity; and that as no heat can exist except by combustion or by friction (unless imported heat, which is itself sustained by combustion or friction), the voltaic arc, the most intense heat, which is not sustained by combustion but exists in all its intensity in a vacuum, can only be the result of friction; and inasmuch as the mass of the metal is not subjected to friction, the friction can only exist in a violent action of the atomic particles of the metal,

Knowledge is of two kinds, positive and negative, namely, that which we know is, and that which we know must be, because it can be nothing else. It is more by the negative than by the positive reasoning that we can determine the nature of electricity. Deschanel, recognizing the crudities of the electric fluid theories, said of the positive and negative currents: "It is conceivable that the two electricities, instead of being two kinds of matter, may be two kinds of motion, or in some other way may be opposite states of one and the same substance." The reasoning by which we establish the verity of this conception is both positive and negative, and the reasoning of analogy.

Washington, D. C. W. E. SAWYER.

Sections 9 and 10, Magnetism and Electricity, are likely to prove two of the most attractive, as they are certainly among the most important. All departments of these subjects—and how varied they are even scientific men may be astonished to learn—are illustrated with great fulness; the number of entries in the Catalogue is 650, commencing with the greatest natural magnet yet known, weighing, with armature, 152 kilograms, sent by the Teyler Foundation, Haarlem, and concluding with a minute description of the Polar Light Apparatus, by Prof. Lemström. Of apparatus connected with Electricity the variety is astounding. Friction and Induction Machines, Galvanic Batteries (there are 32), Thermo-Electric Batteries, Induction Coils, Magnetic-Electric Machines, and other modes of producing Electricity or Electric Currents, are abundantly represented. So, also, apparatus for producing, collecting, observing, regulating, and measuring electricity; of Galvanometers alone there are 43. In the Electrical Section, no doubt the most attractive department to the general public will be that devoted to apparatus for the application of Electrical principles to practical purposes, illustrating, as it does, every stage in the progress of the Electric Telegraph. The Catalogue in this department contains 204 entries of Telegraphic apparatus alone, not to mention the various other applications of electricity to military and other purposes. Nature May 7 '76

VOL. IX., NO. 10. NEW YORK, MAY 15, 1876. WHOLE NO. 205.

A NEW RELATION BETWEEN ELECTRICITY AND LIGHT: DIELECTRIFIED MEDIA BIREFRINGENT.

By JOHN KERR, LL.D., Mathematical Lecturer of the Free Church Training College, Glasgow.

(*From the Philosophical Magazine.*)

The thought which led me to the following inquiry was briefly this:—That if a transparent and optically isotropic insulator were subjected properly to intense electrostatic force, it should act no longer as an isotropic body upon light sent through it. Faraday was often occupied with expectations of this kind; and he has mentioned in his memoir on the Magnetization of Light, and elsewhere in his "Researches," how he experimented in this very direction, upon electrolytes as well as dielectrics, at different times and in many ways, but always without success.* As far as I remember, I have not read or heard of an attempt in this field by any other naturalist. I proceed to offer a few notes of some recent experiments of my own. The investigation is not so complete as I should wish it to be; but it has been carried forward as far as my limited time and means would allow. At present I confine myself to solid dielectrics, reserving the case of liquids for a second paper. The principal results given in this first paper are stated apart, in articles 11, 17, 23.

1. *Dielectric of Plate Glass.*—A piece of good plate glass, ¼ inch thick, is formed roughly, before it leaves the shop, into a rectangular block 6 inches long and 2 wide. In this and subsequent operations, the original polish of the plate is carefully preserved. Two holes, about 1-10 inch wide, are drilled into the block from its opposite ends; they lie exactly as in continuation of each other, in a line parallel to the longest edges of the block, and midway between opposite faces; and they terminate in well-rounded bottoms at the centre of the block, with a short extent (a quarter inch or less) of clear glass between them. Two fine pillars of glass rise from a stand on the table, distant an inch or two from each other. The block is placed across the pillars (at about a foot from the table), its plate-faces vertical, and the line of borings horizontal; and in this position it is tied securely to the pillars by coils of silk thread. Two thick wires of copper, sheathed in gutta-percha, have their bare extremities inserted in the borings, down to the ends. As a provision against the strongest electric action applied in any case, these wires are coated very deeply with lac or sealing-wax at their junction with the glass, and an inch or more outwards. The whole surface of pillars and block is well varnished with lac—except a small space which is left clean upon each of the plate-faces, to allow distinct vision through the centre of the block.

When the dielectric has been thus prepared, its transparency is all that can be desired. Objects bright or faint are seen horizontally through the central parts of the plates (between and around the ends of the borings) quite as well as through a fine window.

2. The electricity is obtained from a Ruhmkorff's induction apparatus, which gives a spark of 20 to 25 centimetres. The dielectric just described stands upon the table close to the inductorium. The outer ends of the wires from the dielectric are screwed into the knobs of the secondary coil. From the same knob two wires are led to the other side of the instrument, and are connected with two insulated metallic balls, which act as spark-terminals. The distance of these balls, or the actual spark length in air, is under the observer's control at every instant.

The ends of the secondary coil are separated thus at one place by so many inches of air, and at another place by a quarter inch of glass. When the primary circuit is closed in the usual way, through the oscillating rheotome of the instrument, the air between the spark-terminals is broken by a sensibly incessant discharge, while the glass between the induction-terminals is traversed by a strong electric force. By simple increase or diminution of the distance between the spark-terminals, the intensity of electric strain thus produced at the centre of the glass block may be raised or lowered at once and in any degree, as the observer pleases. I may mention that on several occasions, when the instrument was working at full power, and the spark-terminals were drawn 7½ or 8 inches apart, strong discharges burst across between the two induction-wires, at the rate of about one per second, without cessation of the principal discharge. The insulation was so good that the dielectric was not in any way damaged. The discharges took place through the air in dense white sparks, from end to end of the block, a distance of 7 or 8 inches. In these circumstances, the part of the glass block between the induction-terminals must have been subjected to a strain little short of the utmost it could bear. Electric forces of such intensity were hardly ever applied in the experiments—were not, indeed, required.

3. The polariscope consists of two Nicol's prisms. A flat paraffin flame, presented edgeways, is used as a source of light. Next to the lamp, and close to it, comes the first Nicol; then, at a distance of two feet or more, comes the dielectric of plate glass; then, at a like distance, comes the second Nicol. The pieces are so arranged that the observer, looking horizontally through the polariscope, and keeping the first Nicol at the centre of the field of vision, sees the flame through the centre of the dielectric, midway between the induction terminals. The light crosses the dielectric at right angles to the plate-faces, and therefore at right angles to the lines of force.

4. *Neutralizing Plate.*—Every very thick plate of glass which I have yet worked with exerts most of its points a slight depolarizing action upon transmitted light. When such a plate is inserted between the two Nicols without compensation, anything like perfect extinction is generally unattainable, and the sensibility of the polariscope is lost.

The principal section of the first Nicol being in any desired position, and that of the second Nicol perpendicular to it, the dielectric (still nonexcited, though connected with the coil) is inserted properly between the Nicols, and the light reappears well in the polariscope.

The neutralizing plate, a piece of glass about six inches square, taken from the same original plate as the dielectric, is then placed upon a stand immediately in front of the second Nicol, and is moved by trial into such a position that the restored light is again extinguished perfectly by a very small rotation of the analyzer. The apparatus is now ready for work.

The highest powers applied in the experiments are sufficiently indicated thus: Battery in the primary circuit, a series of six Grove's or Bunsen's elements; corresponding spark length, 9 or 10 inches; actual spark-length, or thickness of air between the spark-terminals, 6 inches, rarely 7; thickness of glass between the induction-terminals, 3-16 inch. But powers a good deal lower give effects distinct enough.

6. *First Experiment.*—The pieces are arranged in the order and manner just described (2, 3, 4). The spark-terminals are fixed at a distance of 5 or 6 inches; the polarizing Nicol is laid with its principal section at 45° to the horizon; and the analyzer is turned, with the help of the neutralizing plate, into the position of perfect extinction. No piece of the apparatus is now touched, except the commutator, till the end of the experiment.

Looking through the polariscope, the observer closes the primary circuit. In about 2 seconds the light begins to reappear through the dielectric, at its old place between the induction-terminals, very faintly at first; but it brightens continuously for 10, 20, even 30 seconds, till it is almost brilliant. When the primary circuit is now broken by the commutator, the light fades away continuously, at first rapidly, then more slowly, to perfect extinction. The time that elapses (in the latter part of the experiment) between the opening of the primary circuit and perfect extinction in the polariscope depends very noticeably upon the intensity and duration of the electrification, increasing as these increase.

7. The light thus restored by electric action cannot be extinguished again, at any stage of the experiment, by any rotation of the analyzer either way.

8. *Second Experiment.*—The polarizing Nicol is laid with its principal section either horizontal or vertical; the analyzer is turned into the corresponding position of perfect extinction; all the other arrangements and the procedure are as in the first experiment. There is now no regular effect ob-

*Faraday's "Experimental Researches," 2216, p. 951, or Maxwell's "Treatise on Electricity," vol. ii. p. 399.

24

26

is not a very great effort required for extinction at any time during the whole hour of observation.

19. *Ninth Experiment.*—The analyzer is mounted in such a way that it may be moved in different directions at right angles to the beam, without rotation; the other arrangements are as in the fifth experiment. When a good effect has been obtained through the centre of the electric field, the second Nicol is moved about so as to receive the light through different parts of the dielectric.

Keeping first to the perpendicular bisector of the line joining the terminals, the intensity of the optical effect diminishes as the distance from the centre of the field increases; and this is particularly noticeable at first, while the effect is rising; but the action has always the same character, is always neutralized by horizontal tension of the compensator. As far as my means would allow, I have assured myself of the fact that, as soon as there is a good virtual compression of the dielectric at the centre of the field, there is an effect of the same kind, a virtual compression in the same direction, beginning to manifest itself all along the equator, but more faintly as the distance from the centre of the field increases. Out of this equatorial line, and well back from the wires, the direction of apparent compression of the dielectric changes from point to point of the field, and is at some points vertical, perpendicular to the line joining the terminals. Only at points very close to the induction-wires does the compensator fail decisively to extinguish or greatly weaken the restored light.

20. In connection with the preceding facts, I may mention that under certain conditions, in the fifth experiment, the compensator does not extinguish the restored light all at the same time, but produces a very dark broad band, which descends from the outer parts of the field towards the centre, as the tension of the compensator increases. This happens for instance, though not very regularly, when the electric force is very intense from the beginning, and the optical effect is just beginning to show itself; it happens also when the lines of force are inclined to the horizon, so that the fine vertical band of flame seen through the centre of the dielectric crosses the equator of the field at about 45°. In these cases there appears to be an unusually rapid variation of birefringent action through the part examined of the electric field.

I have now done with the dielectric of plate glass. Half-a-dozen other solids were tried; and I will conclude with a short account of the only two of them which gave results worth mentioning. The great difficulty was to get a sufficiently strong superficial insulation, the masses being too small. In only one case, that of Iceland spar, was the dielectric perforated by discharge without giving a clear effect; but I think the crystal had received a predisposing flaw in the operation of boring.

21. *Dielectric of Resin.*—This is a piece very similar to the dielectric of plate glass in form, size, and adjuncts. A quantity of clear amber resin is kept at a gentle fusion for some time till it is free from air-bubbles; it is then poured into a suitable mould and left to cool. Two thick stocking-wires of steel, previously fixed into the mould, along one line through its ends, remain imbedded as induction-terminals in the solid resin, leaving less than one-quarter of an inch of clear dielectric between them at the centre of the block. The polarized light enters and leaves the central part of the block through small squares of thin plate glass, which are in optical contact with the resin, and parallel to each other.

This dielectric, even the best specimen of it, is far inferior to the dielectric of plate glass. It gives evidence of permanent and irregular strain in the neighborhood of the terminals; it exerts a pretty strong photogyric action in the polariscope, separating the blue and red by a small angle; it is also imperfectly transparent for very faint light; but its chief defect is, that it allows a spark-discharge over its surface, a length of 7 inches, before the distance of the spark-terminals has much exceeded 2½ inches. With all these deficiencies, the dielectric of resin gives a definite and regular effect; and the action is contrary to that of glass.

All the arrangements are essentially as in the fifth experiment (14). The block is tied to two insulating pillars of glass; the induction-wires of the dielectric are connected with the knobs of the secondary coil; and the light is seen through the centre of the block; midway between the terminals. A pretty good initial extinction is obtained in the polariscope between the blue and red; the light is then well restored by electric action, and the compensator is introduced between the dielectric and the second Nicol. By tension of the compensator in a direction parallel to the lines of force, the restored light is constantly and distinctly strengthened; and by compression parallel to the lines of force, it is regularly and greatly weakened, though never quite extinguished.

To test the value of these indications, I repeated the illustrative optical experiment (12) with the block of resin put in the place of the large block of plate glass; and the results were satisfactory. I varied the experiment also by manipulating the block of resin itself as a compensator against the small square of compressed glass, the resin being simply pulled or pushed gently at both ends; and the results were equally distinct. The lines of stress being parallel, compression of glass and compression of the resin always reinforced each other, compression of glass and extension of the resin always counteracted each other, but never down to perfect extinction. It is true that these last results might be due more or less to the thin plates of glass which limit the resin. From all the observations, I infer that dielectrization of resin is optically equivalent to tension of the resin along the lines of force.

22. *Dielectric of Quartz.*—This is a plate perpendicular to the axis, made as for ordinary experiments in the polariscope, thickness 4 millims., length 20. Two fine holes are drilled into the plate as in the dielectric of plate glass, their bottoms flat, and with one-sixteenth of an inch of clear crystal between them. Wires of copper are inserted in the borings, and are fixed along with the crystal to simple bearings made of glass rods; and the whole piece is coated very deeply with fused lac, a narrow window being left at the centre of the plate. The action of the crystal in the polariscope is well neutralized by a contrary plate of equal thickness; the other arrangements are as in the fifth experiment. With my rough apparatus, the adjustments are so troublesome that I have executed only one short series of observations, of which I append all the notes preserved.

Distance of spark-terminals ½ inch; a faint but clear restoration of the light from almost perfect extinction; the compensator not working distinctly; the insulation perfect.

Distance 1 inch; the light clearly restored by electric action, and then well extinguished by tension of the compensator parallel to the lines of force. The insulation is now failing, sparks passing occasionally over the service of the lac near the crystal.

Distance ¾ inch; the insulation still defective; the light well restored by electric action and, then well weakened by horizontal tension, and strengthened by compression. From what I have seen in some other experiments, I think that the effects in this case and the preceding may have been produced wholly or partially by slight changes of temperature, due to occasional spark-discharge over the surface of the crystal.

Distance again ½ inch: the insulation again good. In this case it is noticed that, before the electric force is applied, while the body of the light is barely perceptible in the polariscope, there is a short length of it from the apex downwards (due exactly through the center of the electric field) which is perfectly extinguished. By electric action this upper part of the light is restored very clearly, and is then as clearly extinguished by tension of the compensator parallel to the lines of force.

23. Upon the whole, though better experimental results are desirable, I consider it proved that dielectrified quartz (like glass) acts upon transmitted light as if compressed along the lines of force, while dielectrified resin (unlike glass) acts as if extended along the lines of force.

24. *Theory.*—Faraday's views as to the constitution and function of dielectrics apply here very aptly.

When the induction-terminals are charged, the particles of the dielectric throughout the field are electrically polarized, and tend accordingly to arrange themselves end to end, and to cohere in files along the lines of force, just as iron filings do in a magnetic field. As far as this tendency of the polarized particles towards a file arrangement along the lines of force takes effect, there is a new molecular structure induced in the dielectric.

If we neglect the influence of ordinary strains transmitted from point to point of the solid, and assume, as a good first approximation warranted by facts(19), that the change of molecular arrangement at each point is determined solely or principally by electric force at the point, we cannot easily suppose the new structure in a dielectric, originally isotropic, to be anything else than uniaxal symmetrical at each point with reference to the line of force through the point. And, even in the case of an æolotropic body, we may assume, as a simple and sure approximation to the truth, that the effect of electric force is to superinduce a uniaxal structure upon the primitive structure.

The uniaxal structure thus induced by dielectrization has been experimentally detected and characterized by birefringent action in three cases. As a matter of fact, it appears to be negative in glass and quartz, but positive in resin.

The electric force has probably a certain resistance to overcome, something analogous to coercive force in the case of magnetism. A sensible time is therefore required for the development of the uniaxal structure by electric action, and for its disappearance after the electric action has ceased. Under an intense and long-sustained electric force, the new structure of the dielectric may assume the character of a very stiff, and, perhaps, permanent set, analogous to permanent or subpermanent magnetism (18). We shall see afterwards, as might indeed be expected, that there is nothing similar to this in the phenomena presented by dielectrified liquids.

Contrary electrizations rapidly succeeding one another exert contrary actions of electric polarization, but conspiring actions of molecular arrangement; they are therefore as effective as a continued electrization in one direction; and Ruhmkorff's coil is as effective as an electrical machine of equal strength.

Magnetism and Electricity. By FREDERICK GUTHRIE. Collins' Advanced Science Series. London and Glasgow: W. Collins and Son. [Price 2s. 6d.]

THE study of physics is now receiving a greater share of attention than formerly. We have happily grown out of the idea—or are fast growing out of it—that young men should leave college with a marvellous stock of Greek and Latin and a no less marvellous ignorance of the laws that govern the world around them. Of the various branches of physics, few are more attractive than magnetism and electricity. In the hands of an able teacher, they may become an excellent means of mental discipline by awaking a spirit of inquiry and stimulating the powers of observation. To such a teacher, Professor Guthrie's work will be a most valuable aid. The leading principles of the subject-matter are unfolded in plain concise language. There is the felicity of expression and lucidity of idea that at once denote thorough mastership. Nothing really essential is omitted; and but little that may be thought superfluous is introduced. Upwards of three hundred figures are scattered throughout the book, and are what they purport to be, real illustrations. It is, however, to be regretted that some of the more important are not made to scale. Nothing but a long experience with the difficulties generally felt by beginners could have led to such a series of diagrams.

We might instance those illustrating the electrophorus, in which by a simple arrangement of the signs + and —, the successive changes that occur in the electrical condition of the resinous plate and the metallic disc are clearly placed before the eyes of the student. In some other text-books a similar plan is adopted; but in none that we have hitherto seen is this important principle propounded with such sequence and completeness. As another instance, we would mention the explanation given of the development of frictional electricity. By means of arrows, and the usual algebraic signs, the course of the positive and negative electricities is clearly shown.

We believe that a great deal is to be learnt from good diagrams on the twin subjects of magnetism and electricity, just as well as in the various branches of natural history. If Ganot's "Physics" was so popular in France some years ago it owed its popularity in great measure to the excellence of its illustrations, and when a better text with equally good illustrations, made its appearance, Ganot retired into honourable obscurity. We have several text-books that contain finer specimens of the art of the engraver than the one before us, but we do not know another in which so much is done by ingenious diagrams to render tangible—we might say—those points which are the least easily realised by youthful minds.

The work is divided into three books. Book I. treats of Frictional Electricity; Book II. of Voltaic Electricity, and Book III. of Magnetism. The name of the book would therefore more aptly be "Electricity and Magnetism" than *vice versâ*.

In Book I. we think a little too much importance has been given to a few subjects, *e.g.*, the relation of heat to discharge, discharge by flame, by evaporation, &c. We would suggest as a substitute for these pages as many paragraphs elucidating the experiments of velocity based upon the rotating mirror. Electrophorus is spelt in this part electrophoros. So long as phosphorus obtains in chemistry and cryophorus in heat, &c., it seems unnecessary to break the analogy even for the sake of introducing a purism.

Chapter III. in Book II. contains 21 pages; too much stress seems to be here laid on the electrolysis of various salts. If this chapter were reduced to four pages, and the balance used to supplement the rather succinct treatment of telegraphy and magneto-electricity, we believe the book would not be less valuable.

We also regret that the author adheres so strictly to the self-imposed rule of avoiding historical references. The names and labours of such men as Ampère, Oersted, Faraday, Wheatstone, Sir William Thomson, Professor Morse, &c., ought to be familiar to every student.

There is an appendix of nine pages of closely-printed matter, in which directions are given to enable the student to construct for himself a large number of the most ordinary pieces of apparatus both of static and dynamic electricity. This novel feature will be found to serve the twofold purpose of economy and of practical instruction. Indeed there is no better means of getting at the rationale of the science than this.

As this book deserves to be extensively used, we think that another chapter might be added in a future edition. It is not enough to know principles, but we must know how to apply them. For this purpose we would recommend a short collection of numerical problems on the laws of quantity, inverse squares, the method of oscillations, resistances, &c. Such problems are being constantly set at examinations for the requirements of which this book seems admirably adapted. Besides this service such a chapter would evidently lead to a more thorough comprehension of the laws it illustrates.

SPECTRUM OF THE ELECTRIC SPARK IN A COMPRESSED GAS.

M. A. CAZIN.

THE electric spark in a gas is analogous to the ordinary flame of a hydrocarbon. In each of these luminous sources there are gaseous particles which produce a spectrum of lines, and solid or liquid particles which produce a continuous spectrum. These are derived in case of the spark from the electrodes and the sides of the vessel when very near. When the pressure is increased these particles are more abundant, their continuous spectrum becomes more brilliant, and, finally, causes the disappearance of the linear spectrum of the gaseous particles. It is in the flash of fire that things take place thus: the paler luminous halo or aureola is formed of gaseous particles whose linear spectrum is more or less visible; it is to the entire spark what the blue base of the flame of a candle is to the entire flame. At ordinary pressures, in nitrogen, the spark is pale and furrowed with small flashes of fire. We see in the spectroscope the grooves ascribed to nitrogen, and in their intervals the characteristic lines of this gas. On compressing we see the grooves disappear little by little, whilst the continuous ground of the spectrum becomes more brilliant. When the pressure exceeds two atmospheres there are only six lines of nitrogen from the orange to the blue, and five diffused bands beyond. At 10 atmospheres there only remain the two nitrogen lines $\lambda = 567$ and $\lambda' = 500$, and then a very brilliant line in the violet $\lambda'' = 424$, which first appears at 5 atmospheres. The sodium line is very distinct, whilst it is not to be distinguished at ordinary pressures. About 15 atmospheres the spark becomes dazzling; upon the continuous spectrum are seen the four lines above mentioned, and certain brilliant points due to platinum. In air compressed above 30 atmospheres the spark produces intense reddish vapors, and the spectrum showed the absorption spectrum of hyponitric acid.

MR. EDISON'S ELECTRIC DISCOVERY. a

On the evening of Thursday, December 16, Mr. Edison brought his discovery, of what he supposes to be a new force, before the Polytechnic Club of the American Institute. Dr. Beard gave a very lucid account of the phenomena, observed by himself as well as by Mr. Edison; and he pointed out in what particulars the new spark is similar to some forms of electricity and in what it appears to differ from the various known forms of that force. Like a true scientist, he pointed out that only such phenomena as every competent experimenter is able to verify at any time are worth consideration; and he spoke of the sources of illusion and delusion which misled Reichenbach, and afterwards others who asserted that they had verified his alleged discovery of the so-called odic force.

Some writers who gave the first reports of Mr. Edison's discoveries to the daily papers, with more enthusiasm than discernment or knowledge, said that, in their opinions, there was identity between Mr. Edison's discovery with the so-called results of Reichenbach's experiments. But the difference is that in the first case we have a reality, and the experiments have results which any one can see and verify; while in the other case we have alleged results which nobody can see but the mediums, so that all belief in the reality of Reichenbach's phenomena rests exclusively on outside testimony.

Dr. Beard also pointed out a feature to which we referred in an article in our issue of December 25, namely, the dissimilarity of the experiments of Reiss, with what he calls weak sparks, and Mr. Edison's discovery. They differ in origin as well as nature. Reiss' experiments were made with static electricity, while Mr. Edison obtains his results from the contact breakers of electromagnets. Dr. Reiss' weak sparks have polarity, while those of Mr. Edison show none, and in that respect the latter differ from all other known forms of electricity: at least neither Dr. Beard nor Mr. Edison have been able to discover any trace of polarity, but, as this is only a negative proof, and we do not know what future investigations may reveal, it is as yet premature to give a decided opinion.

After considering Dr. Beard's elaborate and masterly exposition of the phenomena thus far observed, and seeing the experiments which Mr. Edison kindly exhibited before the members of the Polytechnic Club, with his apparatus of three vibratory sounders, charged by six chromic acid battery cells, we see no reason to change the opinions we have already expressed: That, after all, the phenomena may be due to a peculiar form of induction. They prove that the inductive power of a coil, when charged or discharged by a sufficiently strong voltaic battery, extends all around to a distance of one or more inches, and can not only induce currents in other coils, but also in straight wires or, better, in metallic bars, kept within the range of this influence, which influence may be called an inducing atmosphere surrounding the coils. Dr. Beard also appears inclined to the view that the phenomena are due to electricity; while Mr. Edison differs from him on this point, and is strongly inclined to consider the phenomena to be due to a new force, as distinct from electricity as light or heat is. Mr. Edison would rather prefer to consider it as a new form of heat or light than of electricity, and gives, as his principal reason for this view, the absence of polarity, which absence exclusively belongs to heat and light, while electricity without polarity is (to use one of Herbert Spencer's expressions) unthinkable. We fully agree with him in this respect; and according to Mr. Edison's invitation, we will assist him in a new course of experiments, laying the results before our readers at an early opportunity.

(24) A. G. T. says: I have constructed a Jamin magnet, but have failed in magnetizing it on account of its peculiar shape and form, not having been able to apply the electro-magnet to the surface of the steel ribbons. Wishing to construct a magnet of great power, I ask your advice how I am to proceed in magnetizing it. What power of battery, and what form of magnet am I to use? A. We think you should be able to charge it with a bar electro-magnet. Two or three large sized cells will magnetize the latter strongly if the coils are properly constructed.

MAGNETIC OBSERVATIONS IN CHINA

THE first annual report of the magnetic observations at this new observatory has just reached Europe, and it contains results of considerable interest to those engaged in the study of terrestrial magnetism.

The position of Zi-ka-wei is 31° 12' 30" N., and 8h. 5m. 45s. E. of Greenwich, being rather less than four miles to the S.W. of Shang-Hai. The observatory is in possession of an excellent set of instruments for determining the absolute values of the magnetic elements, procured by the kind assistance of the Director of Kew Observatory, and a set of self-recording magnetographs by Adie, verified at Kew, have just been erected in a suitable building. The observer, the Rev. M. Dechevrens, S.J., spent a considerable time at Stonyhurst Observatory previous to his departure for China, in order to make himself thoroughly acquainted with the methods of observation, and with the use of the instruments.

The observations in the report extend from April 1874 to March 1875, and furnish the following data for the epoch Oct. 1, 1874:—

Declination ...	1° 54'.72 W.
Dip ...	46° 15'
Total Force ...	10.04850

The value of the declination is very reliable, as it depends on observations taken every half hour from 6 A.M. to 6 P.M. on four days each month in 1874, and on eight days a month in 1875. The dip results from six complete observations, and the horizontal component of the intensity was determined twice a month in 1874, and every week in 1875.

Previous dip observations at Shang-Hai, by Sir E. Home in 1843, and by Capt. Shadwell in 1858, give − 2'.2 and − 3'.4 as the secular variation for 1851 and 1862, the latter differing but slightly from the present variation in England.

Comparing the monthly means of the horizontal force for the winter and summer of 1874-75, we find an excess of 0.00074 in favour of the winter, when the sun is nearest the earth. The extreme variation is only 0.00577, and both maximum and minimum occur in the summer months.

From a limited number of night observations it appears that the range of the declination needle is much more confined, whilst the sun is below the horizon than during the day hours. The diurnal variation is regular throughout the year, but the daily changes in winter are less simple than those of summer. The following are the mean results for the separate seasons:—

	Mean.	Min. at		Max. at	
Spring ...	1 50 49	9 A.M.	1 47 33	2 P.M.	1 51 3
Summer ...	1 49 39	8 "	1 45 45	2 "	1 53 3
Autumn ...	1 59 35	9 "	1 58 9	1 "	2 1 10
Winter ...	1 58 51	9 "	1 57 32	1 "	2 0 5

The time of the principal minimum is more constant than that of the maximum, the latter being anticipated by one hour in winter.

A sudden change from 1° 50' 13" on Sept. 21 to 1° 56' 51" on Sept. 26, 1874, seems to require further confirmation (which it did not receive in 1875) before it can be considered as more than accidentally connected with the passage of the sun through the autumnal equinox.

The monthly mean value of the declination is greatest in November and least in June, and the absolute maximum and minimum were:—

2° 3' 49" at 11h. 15m. A.M. on November 8,

and

1° 41' 58" at 9 A.M. on June 29,

giving a yearly range of only 21' 51", whilst the secular variation amounts to + 5'.85. The value on Nov. 8 was also evidently increased by some irregular disturbance.

The comparison of the yearly means for the different hours with the hourly means for each season, shows that the sun's position with regard to the equator has a decided effect on the magnetic declination, an increase and diminution in summer invariably correspond with diminution and increase in winter.

In discussing the hourly velocity of the needle, it is found that the acceleration is greatest between 10 and 11 A.M., when the magnet is near its mean position, and that the A.M. maximum velocity is an hour earlier, and the P.M. maximum an hour later in summer than in winter, the greatest velocity being about 1'.5 per minute.

The mean amplitude of the daily excursions of the declination magnet is 7'.88 in summer against 3'.68 in winter, June giving the maximum mean amplitude of 9'.06, and December the minimum of 2'.95. The value of 1'.92 in February appears to be exceptional. The greatest extent of a daily oscillation in the course of the twelve months was 11'.05 on June 1, and the least 1'.13 on Feb. 20, giving a maximum yearly variation of 9'.92.

The changes of the magnetic elements appear to be remarkably small throughout, and very free from irregular disturbances. The care with which the observations are taken, and the efficient way in which they are discussed, are an earnest of the plentiful harvest we have every reason to expect from this land once so famous, but hitherto so neglected by modern science.

THURSDAY, FEBRUARY 17, 1876

THE LISBON MAGNETIC OBSERVATIONS

Annaes do Observatorio do Infante D. Luiz. Magnetismo Terrestre. Lisbon Imprensa Nacional. (1870, 1874)

THAT in 1858 Portugal entered into "the Magnetic Union of Nations, founded by Gauss and by Humboldt in 1832," was due to the enlightened solicitude of the King Luiz I. for the progress of science. The observatory founded by him at Lisbon, and placed under the care of the late Mr. de Silviera, has during the last years been directed by Mr. de Brito Capello, who had previously the oversight of the magnetic department, and to whom we believe the results in the two parts of Annals before us are chiefly due.

The value of the Lisbon observations and of these results is so much the greater that the neighbouring country, Spain, has done nothing for terrestrial magnetism, and even France, which stands so high in science, has given us no such series of observations since Arago originated them by the devotion of years to the movement of the magnetic needle.

The first part of the Annals before us (1870) treats of the results for the magnetic declination derived from direct observations made at 8 A.M. and 2 P.M. (1858-1868), and for the diurnal variations (1864-1868) from a photographic registering apparatus similar to that at Kew. The secular variation is first investigated. This mysterious movement, which we can attribute to no known cause, as it has no known period, is shown at Lisbon by a mean approach of the north end of the needle to the north at the rate of 5'.9 a year during ten years, but varying from a minimum of 4'.8 in 1858-9, to 8'.2 in 1866-7. An annual law has also been found consisting of an oscillation of 1'.5, the needle being nearest the north in June, and farthest from it in December and January.

The diurnal variation at Lisbon resembles to a considerable extent that obtained at more northern stations in Europe. The periodic variation of the mean range of this oscillation, first discovered by Dr. Lamont, which occupies from ten to twelve years, has also been found at Lisbon. This investigation has its importance increased by the fact that the greatest and least mean oscillations happen at the same times as the maximum and minimum frequency of solar spots. The coincidence first indicated by Sir E. Sabine, with reference to magnetic disturbances, was remarked independently by Dr. Rudolph Wolf, of Zurich, who has made it the subject of an extensive and valuable series of investigations. Dr. Lamont, commencing with Cassini's observations, has found the mean duration of the magnetic period to be 10.43 years, while Dr. Wolf obtains 11.11 years from a longer, though perhaps less certain, series of solar spot observations. Since there can be no doubt that the yearly variation of sun-spots and of the amplitude of the diurnal oscillation of the magnetic needle follow the same law and depend on the same cause, every new determination of the epochs of maxima and minima is of value, fixing points which will determine the mean duration and variable length of the period, and thus probably lead us to a knowledge of the common cause. The Lisbon observations give 1859.9 and 1867.0 as epochs of maximum and minimum, agreeing very nearly with those derived from the Munich and Trevandrum observations. In the determination of the mean duration, everything depends on where we commence. If we begin with Arago's magnetic observations, the mean duration is about 10.7 years; if we take the most accurate results for the sunspot area from Messrs. De la Rue, Stewart, and Lœwy, we find 11.2 years, nearly that deduced by Dr. Wolf. Evidently a much longer series of accurate observations is required to determine the length of a period which has varied between 8 and 12.3 years within the last half century; though we believe Dr. Lamont's result to be nearly true.

As the Observatory establishment was not sufficient for the long calculations required for the investigations connected with the lunar diurnal variation, the latter was sought approximately from the effects of the lunar action in diminishing or increasing the solar diurnal oscillation at different days of the moon's age. It was thus found that the diurnal oscillation from 8 A.M. to 2 P.M. was greatest when the moon was three and eighteen days old, while it was least when she was ten and twenty-four days old. This indicates a semi-diurnal oscillation due to the moon's action, with an amplitude of 1' nearly, having the maximum westerly positions when the moon is near the upper and lower meridians.

It is remarked by Mr. Capello, with reference to disturbances, that in many cases the observations taken as disturbed (those differing from the normal position by 2'.26 or more) were, properly speaking, not disturbed observations, but belonged to very regular curves, in which the morning minimum was more marked or the afternoon maximum was less so than usual. Whereas disturbances are shown by serrated curves. This remark is quite exact, and the fact becomes even more marked in lower latitudes. The investigation for the lunar variation just noticed will show one cause for this variation of the amplitude of the diurnal oscillation which is greater the greater the lunar action.

The second part of the Annals before us (1874) contains the discussions for the other magnetic elements. Mr. Capello finds, from nine years' observations, that the horizontal force of the earth's magnetism was greatest in July, least in September, with a secondary maximum in November, and minimum in February. This result depends on few observations, but approaches considerably to that obtained first at Makerstoun. The very marked minimum found for the month of September induced Mr. Capello to examine whether this might not be due to the action of disturbances, which in general diminish the earth's magnetic force; it results from this discussion that though the disturbances have a considerable effect in increasing the amplitude of the annual oscillation, yet the maximum in December is best marked in years of least disturbance. This result he confirms by an examination of the Kew observations, and it agrees with that deduced from each of a series of years' observations of the bifilar at Makerstoun. Mr. Capello also finds that the Munich observations show the most marked minimum in September and October, in years of least disturbance. It is an important fact, confirmed by the results from many observatories, that the horizontal force of the

32

Lisbon Magnetic Observations

MR. DE BRITO CAPELLO, Director of the Lisbon Magnetic Observatory, having addressed to me several interesting results having reference to the notice of his observations which appeared in NATURE, vol. xiii. p. 301, I am anxious to communicate them to your readers.

With reference to the movement of the declination magnet from 8 A.M. to 2 P.M., Mr. Capello gives me the following mean values for each year from 1858 to 1875:—

1858	8·74	1867	6·15
1859	10·54	1868	7·17
1860	10·11	1869	8·42
1861	9·00	1870	10·83
1862	7·81	1871	10·60
1863	7·65	1872	9·45
1864	6·91	1873	8·22
1865	6·61	1874	7·23
1866	6·19	1875	6·09

These quantities, Mr. Capello remarks, show the maxima 1859·8 and 1870·9, and the minimum 1867·1, agreeing very nearly with the epochs of maximum and minimum sun-spots.

It also appears as if the minimum had been reached again last year, the mean oscillation (6·09) being less than in 1867. This agrees with the conclusion derived by me from the Trevandrum observations, and communicated to the French Academy of Sciences last year. Dr. R. Wolf had previously (as I now find) concluded from his sun-spot observations that the minimum would probably appear in 1875-6; and he considers we have now one of the short periods, which his tables of sun-spots show may be expected every 80–90 years. My own conclusion to the same effect (that we have now a short period) was founded on a consideration of the magnetic observations. The last short period was that from the maximum 1829·7 (shown by Arago's observations) to that of 1837·5 (shown by Gauss's observations), an interval of rather less than eight years. If we may take 1875·5 as the epoch of the present minimum, then the interval from the last is nearly nine years. As the interval from the minimum of Arago (1824·2) to the next was nearly 9·2 years, we find a space of nearly forty-two years from the last short period to this one. Should this hold for the next maximum it will occur about 1879·0.

Mr. Capello has obtained the interesting result that the curve showing the mean diurnal disturbance of the vertical magnetic force is the exact inverse of that for the mean diurnal disturbance of declination at Lisbon; a movement of the north pole of the declination magnet towards the west corresponding to one downwards of the south pole of the balance needle. It appears also that the difference of sign in the temperature coefficient for the balance magnet due to changes of the compensation bar from brass to zinc and zinc to brass, on which a remark was made in NATURE, vol. xiii. p. 302, does not affect the results for the diurnal variation, each year giving the same mean law of a minimum vertical force between 11 A.M. and noon, and a maximum near 5 P.M. whatever the sign of the temperature coefficient. It appears also that the results at Lisbon are confirmed by those obtained at Coimbra, ninety nilles to the north.

JOHN ALLAN BROUN

How can I make a conductor to draw off frictional electricity? A. Brush some gum water over the outside of a base ball. When this is almost dry, roll the ball on gold leaf so that the ball will be covered with a smooth layer of gold; then mount the ball on a stick of sealing wax, set in a little wooden disk or base. Then on one side of the equator of the ball insert five or six cambric sewing needles, so that they will be about ⅛ inch apart; these needles act as a comb to conduct the electricity to the gold leaf on the ball, from which the electric sparks may be drawn. In some establishments where leather belts are run at a very high speed, electricity is produced on the belts. If the conductor that we have just described be placed with its row of needles near to, but not touching, one of these belts, the electricity of the belt will be accumulated, and will manifest itself in the form of the bright blue sparks, several inches in length, that pass from the conductor to the knuckle of the hand that is presented to it.

THE EFFECTS OF THE SUN'S ROTATION AND THE MOON'S REVOLUTION ON THE EARTH'S MAGNETISM

WHEN the mean horizontal force of the earth's magnetism for each day of the year has been deduced from well-corrected observations of the bifilar magnetometer, and the results have been projected in the usual way, the curves thus obtained show successions of maxima and minima occurring in some instances at nearly equal intervals and in others abruptly and apparently without law. It has been found that these changes are experienced similarly at all stations where observatories have been placed on the earth's surface; they are therefore variations of the magnetic force of the whole earth. The results now considered, though derived from the observations at a single station, may thus be accepted as true generally for all places.

In the projection of the daily mean forces observed at Makerstoun in 1844, the first and last quarters of the year showed large oscillations of the earth's magnetic force, the maxima occurring near the times of new moon and the minima near those of full moon; the ranges of the oscillations were not equally great, and the oscillation disappeared in the months near midsummer. The mean result for the whole year seemed to show that great changes of the earth's magnetic force were due to the moon's position relatively to the earth and sun; but no explanation could be offered for the apparent irregularities in the lunar action. Eleven years later (in 1857), while discussing observations made near the equator, I became persuaded that the variations in question were really due to the sun's rotation on his axis. The result of a re-examination of the Makerstoun observations gave a mean period of nearly twenty-six days for the most probable duration of the magnetic oscillation.

Astronomers who till then had occupied themselves with the determination of the time of the solar rotation had found for it from 27·3 to 27·7 days. It was difficult, in the face of this result, to suppose that the magnets were better acquainted with the true time of the sun's rotation than the eminent observers, who, with the best telescopes, had watched the movement of the solar spots; and it was suggested that a movement of the sun's magnetic poles might explain the difference of the periods obtained. More recently, however, it has been found that the spots give considerably different times for the sun's rotation, and especially that those nearest the solar equator indicate, as Spoerer has shown, a period of 26·3 days, thus approaching nearly to that obtained previously from the magnetic observations. Dr. Hornstein, director of the Prague Observatory, discovered, independently, nearly the same period from his observations in 1870.

There still remained for explanation the irregularities already noticed in the lengths and ranges of single oscillations. I, on a reconsideration of all the discussions previously made by him, arrived some time ago

---

Influence of Heat upon Magnetisation.—M. J. M. Gaugain.—M. Favé had pointed out that when a bar of steel is magnetised at about 350°, allowed to cool, and heated again, the quantity of magnetism augments, and may reach triple the value which it had preserved after cooling. M. Wiedemann maintains that a bar magnetised at an elevated temperature loses on cooling a part of its magnetism: it loses a further portion when heated again, but on cooling it resumes a part of what it had lost. The author believes that this contradiction is due to the circumstance that M. Wiedemann experimented only with bars heated to 100°, whilst M. Favé operated with bars magnetised at a far higher temperature.

77

---

at the conclusion that the results obtained for the solar and lunar actions did not exclude each other, but that both sun and moon were concerned in the changes of the earth's magnetic intensity; and that possibly the variations in the character of the single oscillations were due to the sun and moon sometimes acting in the same and sometimes in opposite directions; just as in the case of the oceanic tides, for which the differences would be even greater were the solar more nearly equal to the lunar action.

This conclusion is put to the test; the mean variations derived from the observations for each of two successive years are calculated for periods of 26, of 27·3, and of 29·53 days, the two latter being the times of the lunar, tropical, and synodical revolutions respectively. The variations for each of these three periods corresponding to the positions of the moon and of a given solar meridian for each day of the year are then added together; the sums should represent the total actions of the two bodies for each day, and if no other causes are in question, they should agree with the observed variations.

I have shown that when the calculated results are projected so as to form a red curve, on the same mean line as a black curve representing the observations, the two agree very nearly with each other throughout the two years. The different durations and ranges of single oscillations, and the total disappearance of the latter in certain months, are found to be produced, as was supposed, by the greater or lesser agreement or opposition of the three actions.

These results demonstrate, I think, not only that the sun's rotation and the moon's revolutions produce variations of the earth's magnetic force, but that all the marked variations are really due to these causes.

There appears to be one exception to the generality of this conclusion, in sudden great changes, generally diminutions, of the earth's magnetism, which appear of variable magnitude and apparently at irregular intervals. I have examined these cases, and find that if a considerable diminution of intensity happen suddenly when a given solar meridian is in the same plane with the earth, that a similar sudden diminution generally occurs twenty-six days or some multiple of twenty-six days after, when the same solar meridian and the earth are again in the same plane. In one case the sudden loss of force begins five times in succession at the exact interval of twenty-six days.

If we examine these cases of successive disturbance when a given solar meridian arrives opposite the earth, we are induced to conclude either that the solar action exists only for this position, that is to say, that the earth is its cause; or that the action is continuous, but, unlike light and heat, is propagated only in one direction (or plane); or, which seems more probable, that the medium through which these actions are transmitted proceeds from the sun, is not uniformly distributed around it, nor always distributed in the same way. This idea may aid in explaining many facts in terrestrial magnetism for which hitherto no clue has existed.

We arrive then at the conclusions that the variations of the daily mean magnetic force are due to causes external to the earth, depending on the sun's and moon's motions; that all the principal variations of this force can be calculated approximately for each day in twelve months, on the hypothesis that the actions of these bodies are constant throughout the year for the same positions relative to the earth; and that the great magnetic disturbances (accompanied by the aurora borealis) are due to actions proceeding from certain parts of the sun's surface, since so many of them repeat themselves at intervals of twenty-six days, when the same solar point returns opposite the earth. It appears from other investigations that the sun's rotation produces marked effects on our atmosphere.

20. *Des grandeurs électriques et de leur mesure en unités absolues*, par E. E. Blavier. (Ann. télégr., tome I, page 9, 287. Tome II, page 140, 250).

La publication de cette importante étude n'était pas encore terminée avec la dernière livraison de 1875 des Annales télégraphiques. L'auteur part des travaux qui ont été entrepris en Angleterre pour déterminer l'unité absolue de résistance électrique et dont le résultat était la « B. A. Unit » ou l'« Ohmad ». Après un résumé historique, il discute la question du potentiel électrique et celles de la condensation, de la capacité électrostatique des différents électromètres et de leur emploi ainsi que des condensateurs étalons.

25. *Théorie des galvanomètres*, par H. Weber. (Ann. de Poggendorff, vol. CLIV, page 239).

On est arrivé par l'expérience et la pratique à construire des galvanomètres extrêmement sensibles; mais cet instrument étant indispensable pour toutes les observations et les applications de l'électricité, il mérite bien qu'on en approfondisse le plus possible les conditions théoriques. C'est ce que M. H. Weber a cherché à faire dans l'article sus-mentionné qui ne forme que la première partie d'une étude dont la suite n'a pas encore paru. (Nous rappelons à cette occasion les articles de M. Schwendler sur le même sujet publiés par notre Journal, dans les numéros 15 et 16 du 25 Mars et du 25 Avril 1873).

245

Les recherches théoriques de M. Weber l'amènent à cette conclusion que pour qu'un galvanomètre atteigne son maximum de sensibilité, il doit être établi de façon que sa résistance soit, par rapport à la résistance extérieure du circuit, dans la même proportion que le diamètre du fil nu de son manipulateur au diamètre du même fil recouvert. Un cas spécial dont l'examen présenterait serait l'établissement d'un galvanomètre avec une pile thermo-électrique comme source d'électricité. La première partie du travail de M. Weber ne fait qu'indiquer cette question dont l'examen paraîtra sans doute dans la continuation.

Notices of Books.

Magnetism and Electricity. By Frederick Guthrie, Professor of Physic at the Royal School of Mines: William Collins, Sons, and Company, 1876.

Whether or not there is an opening for another text-book of a purely theoretical nature upon the

subject of "Magnetism and Electricity" is a question upon which different opinions may be entertained, more especially since it is borne in mind that a twelve month has scarcely elapsed since Mr. Fleeming Jenkins' work was published in Messrs. Longmans' series. Still the demands of rival publishers appear to over-ride every other consideration, and we have here in Messrs. Collins' Advanced Science Series, as an extra volume too, "Magnetism and Electricity," by Professor Guthrie.

In the preface, which is written apparently on the "brevity being the soul of wit" principle, we are informed that "this work is intended for the general student." The wants of the "general" student are now-a-days well looked after, and there is a plethora of manuals and text-books. The publication of a new book, if an indication of a demand, is a healthy sign of the times.

In a text-book we do not look for any new facts in connection with the subject: what we do look for, and have a right to demand from whoever undertakes the work, is that the existing facts shall be made as clear as possible that the diagrams shall be such that they can be followed with ease, and that some show at least of logical treatment should be made in the arrangement of the various branches of the subject. Departing from the general custom, Professor Guthrie postpones the subject of magnetism until that of electricity is dealt with. We do not object to this, provided any apparent advantage is to be gained by it. So far, however, from this being the case, the reverse is true, for some knowledge of magnetism on the part of the general student must be assumed before it can be expected that he will successfully grapple with the intricate problems of the electrical relations between currents and magnets, or the measurement of the strength of currents; and on this ground alone, if on no other, we are of opinion that magnetism ought first to be brought under his notice.

The treatment of the work, regarded as a whole, might be improved. At the very commencement we are referred to "Appendix I" for an explanation of the manner in which shell-lac varnish is to be made; frequent reference is then made throughout the book to "Appendix," although the fact has been apparently overlooked in these foot-notes, that there is an appendix and an appendix; so much so, that after being referred to on the sixth page to "Appendix V." for the steps to be taken "to make a balanced glass tube," we are, on turning thither, simply advised to "see Appendix B 1 (b)." An appendix of any kind is an objectionable feature in a text-book like this. If it contains matter of any value, then that ought to appear in its proper place in the text; if the matter is superfluous, and not considered worthy of a place in the text, then it should be dismissed from the work altogether, and not tacked on in this fashion to the end of it.

In a scientific text-book no point should be more carefully attended to, although, strange to say, none is more generally neglected than the employment of new terms only after they have been thoroughly defined and their meaning made clear to the reader. This does not form an exception to the general rule, and the student very soon finds himself landed in the midst of a mass of "electro-inducible" matter, "equipotent," "electrogens," and the like. Why "insulaters" again have to make way for "isolators," or the term "commutator" to be sacrificed for "rheotrope," we are at a loss to understand, and we had as soon expected to find Mr. Frank Buckland writing of the hippopotami in the Zoological Gardens as to find Professor Guthrie writing of "continuous electrophori."

The first part of the book deals with frictional or static electricity.

The second part on voltaic electricity, opens with an account of the "Sources of Voltaic Electricity," and the origin of the current is dealt with at some length. We cannot say that Professor Guthrie has been altogether successful in placing clearly before the student the rival contact and chemical theories. Galvanic batteries form the subject of one chapter, and they are treated in what we may now regard as the stereotype fashion. Daniell's battery occupies the position to which it is in every respect entitled. It is first brought under notice, and the arrangement is described at some length. Why Groves' and Bunsen's should next be brought forward, and in company with Daniell's, regarded as *the* batteries in preference to all others, we are at a loss to understand, unless it be that in this case it was deemed undesirable, from the usual method which has hitherto been adopted, of handling the subject. Under the "Other forms of Battery," which, "though not new or yet in general use, are either of historical interest or involve ideas which may hereafter be developed, or which are applicable for special purposes," are included the Leclanché, which is now in general use for telegraphic work in England and France, and the Gravitation which in one or other of its numerous forms are more or less employed in many parts of the globe; the Minotto, is in general use in India, and Messrs. Siemens' and Halske's modification is all but universally adopted in Germany and on the Indo-European lines. Professor Guthrie, in the short allusion to Leclanché's battery, falls into the mistake, by no means uncommon, of speaking of "the elements being zinc and carbon, and the liquid a solution of chloride of ammonium." Mons. Leclanché, writing of his battery, says: "The peroxide of manganese in possessing a certain conductivity of a considerable amount, and analogous to that of the metals, caused me to think of the probability of constructing a constant one-liquid battery by employing a plate of that material as the positive element," and further on, he adds, "In practice, I replaced the plate of peroxide of manganese by pounded peroxide, which I enclosed in a porous pot; the positive electricity of that mass is gathered by means of a plate of carbon." The battery is a one-fluid battery, and is practically a zinc-peroxide of manganese couple, immersed in a solution of the chloride of ammonium.

We turned with interest to the section on the "Amalgamation of the Zinc Plates," for the purpose of learning what opinion so high an authority as Professor Guthrie entertained on this oft-vexed question. We cannot do better, perhaps, than give in full the explanation which is put forward. In Section 163, page 141, we read: "In fig. 133, E represents an easily, and D a difficulty (*sic*) attackable piece of zinc forming one piece. The arrows represent the direction of the current. *A coasting trade.* Such a heterogeneous piece of

Si l'on suspend un barreau d'acier à un aimant, l'on peut, en chauffant le barreau et en le laissant refroidir ensuite, tout en maintenant toujours son contact avec l'aimant, augmenter le magnétisme permanent que l'on a produit. Si, par contre, le refroidissement a lieu quand le barreau est éloigné de l'aimant, alors le magnétisme permanent est moindre que si l'on n'eût point du tout chauffé. Ce phénomène correspond très-bien avec l'idée généralement répandue de la force coërcitive du fer.

6. Sur les quantités de magnétisme et sur la situation des pôles dans les aiguilles minces, par E. Bouty. (Comptes-rendus, tome LXXX, page 879).

Les vrais pôles des aiguilles minces se déplacent avec l'augmentation du magnétisme; ils s'approchent de plus en plus de l'extrémité de l'aiguille, mais ce déplacement s'accomplit entre des limites très-étroites.

7. Expériences sur l'imitation artificielle du platine natif magnétipolaire, par Daubrée. (Comptes-rendus, tome LXXX, page 526).

Entre autres métaux, le platine de l'Oural contient souvent du fer et se comporte alors comme un aimant, ayant fréquemment des pôles multiples. Le prince Nicolas de Leuchtenberg possède une pareille pépite magnétipolaire du poids de 3,833 grammes. L'auteur a essayé, par la fusion du platine avec du fer, de produire des masses magnétiques analogues aux aimants naturels et il y a réussi en donnant à la masse la forme d'une barre et la direction du méridien magnétique et en la laissant refroidir dans cette position. Il est probable que tous les aimants naturels ont une origine semblable.

8. Sur une nouvelle source de magnétisme, par Donato Tommasi. (Comptes-rendus, tome LXXX, page 1007).

Lorsqu'on fait passer un courant de vapeur d'eau sous une pression de 5 à 6 atmosphères à travers un tube de cuivre ayant 2 à 3 millimètres de diamètre et roulé en spirale autour d'un cylindre de fer, celui-ci s'aimante tellement qu'une aiguille de fer, placée à quelques centimètres de distance de l'aimant-vapeur, est attirée vivement et reste magnétisée pendant toute la durée du passage du courant de vapeur d'eau à travers le tube de cuivre.

9. Observations sur la nouvelle source de magnétisme signalée par M. Tommasi, par Mamnené. (Comptes-rendus, tome LXXX, page 1138).

L'auteur ne croit pas à une nouvelle source de magnétisme. Il croit que dans l'expérience de Tommasi, magnétisme est développé par l'électricité thermique se forme dans le tube de cuivre, par suite de la érence de température de ses deux surfaces.

GRAVITATION AND ELECTRIC ACTION.

M. A. Picart.

the phenomena of the universe may be explained by and motion *alone* without *forces acting at a distance*. s purpose it is sufficient to imagine infinite space filled ernal matter consisting of a mass of atoms animated rpetual movement in all directions. This matter, the atum of the world, is what is commonly called *ether*. t has been hitherto regarded as a fluid whose mole- have in a state of equilibrium fixed relative positions, exerting upon the neighboring molecules a repulsive which give rise to vibratory movements whenever quilibrium is disturbed by any cause whatsoever. rding to the new theory of gaseous fluids (Clausius) ay henceforth conceive the ether as formed of *elastic* s moving with considerable speed in all directions, producing at each point by their impacts upon an elemental plane a determined pressure. From this conception of the ether, which in nowise contradicts ancient view, and which even includes it as a corollary *orie mécanique de la chaleur*, de M. Briot), gravitation nce follows, *i. e.*, the mutual attraction of two material ts in the ratio of their masses, and inversely as the re of their distance. As to electric actions they may explained in an analogous manner. The material cules in arranging themselves by their mutual attrac- so as to form bodies must condense around them- s the ethereal atoms as atmospheres more or less e, the elasticity of which must vary according to the ive positions of the molecules of the body. These the atmospheres whose increases or diminutions of lty or of elastic force constitute the electric condition sitive or negative—of the body. Between these atmo- res and the material molecules situate at a distance must be exerted a gravitation like that of two rial molecules. Between two condensed atmospheres ther a repulsive action must be exerted, resulting from necessary increase of the speed of the atoms which ve in both directions from the one atmosphere to the er, and which produce upon each of them, on the side ere they strike, an augmentation of pressure tending to move them from each other. From these reactions we ally arrive at Coulomb's law of attraction or repulsion; e basis of all electrical theory.—*Comptes Rendus.*

[20271.]—Speed of Electricity.—This is a question to which it is scarcely possible to give even an approximate answer, because so much depends upon the kind of circuit employed. In his celebrated experiment with a Leyden jar, Wheatstone found the velocity of static electricity to be 288,000 miles per second (greater than that of light), while at the other end of the scale we have the speed of maximum current in deep-sea cables, which is under 1,000 miles per second, owing to the enormous amount of lateral induction. Almost any speed between these two extremes could be obtained by suitable conditions of circuit, so "J. G. R. H." may choose which he likes the best, and calculate the time of traversing 25,000 miles for himself.—Beacon Lough.

[20310.]—Magnetising Endless Ring.—You could permanently magnetise a steel ring in the way you describe, but you need not press very hard or you would spoil your magnet. Also notice that the poles would be on the two outside edges of the ring —that is to say, suppose the ring were lying flat on a table, the part in contact with the table would be one pole, and the part looking upwards would be the other, while the inside and the periphery would be neutral and powerless. Such a magnet would, I think, soon lose strength.—Du Fay.

[20310.]—Magnetising an Endless Ring.—About twenty years ago I had a steel ring forged, to which a wooden case was fitted; this case consisted of a circular groove into which the steel ring dropped freely; the outer edge of the case was graduated to spaces of 22½°. When this apparatus was finished the ring, with a distinguishing mark on it, was tested by being placed on a tripod, the mark successively brought to each graduation, and the deviation of the needle of a small mariner's compass noted. On projecting the readings in a curve a weak magnetism was detected; on bringing a somewhat large horseshoe magnet near the ring, not in contact, the magnetism of the ring was exalted, and a much bolder curve obtained. By operating in this manner changes of magnetism in the ring may be observed.—W. H. Hunt.

Magnetism and Electrici... Professor of Phys... Mines: William ... 1876.

Whether or not ther... text-book of a purely...

Après avoir fait l'historique de la machine depuis son invention en 1865 par Holtz, ainsi que de la première modification en 1866 apportée par l'inventeur lui-même, celui des machines de Töpler et de Bertsch, de la machine à deux disques tournants de Holtz, des modifications consécutives de l'inventeur, de Kundt et Carré, des machines doubles de Kaiser et Poggendorff et des modifications ultérieures de Leyser et Musaeus, l'auteur donne le compte-rendu des résultats qu'il a obtenus avec des disques en ébonite, tant avec la machine simple qu'avec la machine double. Il arrive aux conclusions suivantes, que l'ébonite se recommande comme matière pour former les disques des machines de Holtz, parce que la masse en est bon marché, facile à travailler, non cassante et moins influencée par l'état hygroscopique de l'air que ne l'est le verre, tandis que le pouvoir électrique est à peu près le même pour les deux substances.

5. *Quelques essais pour le perfectionnement de la machine de Holtz*, par W. Holtz. (Poggendorff Ann., vol. CLVI, page 627).

6. *Transformation de l'étincelle de la machine de Holtz*, par A. Demoget. (Comptes-rendus, tome LXXXI, page 140).

Lorsqu'on place, dans le courant de la machine une bobine de résistance dont les doubles spires sont bien isolées, on obtient des étincelles entourées d'une auréole, comme celles de la bobine de Ruhmkorff.

7. *Sur les étincelles faibles*, par P. Riess. (Poggendorff Ann., vol. CLVI, page 378).

On obtient avec la machine de Holtz les étincelles faibles en donnant aux électrodes différentes longueurs ou en approchant une pointe de charbon de l'électrode positive ou en suspendant tout simplement un fil de cuivre recourbé à son bout libre sous forme ovale. Tous ces procédés ont pour résultat de rendre l'électricité positive plus faible que l'électricité négative. Le passage de faibles étincelles ne produit pas une augmentation de la température et ne développe pas non plus de magnétisme, tandis que les étincelles ordinaires sont accompagnées de ces deux effets.

Note. La machine de Holtz se charge très-facilement si l'on frotte la plaque d'ébonite avec de l'amalgame. L'ébonite devient électrique positivement. (Poggendorff Ann., vol. CLIV, page 643).

Lois de l'électricité.

1. *Sur les mouvements de l'électricité dans les corps de constitution moléculaire*, par W. Weber. (Poggendorff Ann., vol. CLVI, page 1).

Développement des lois établies par l'auteur en 1846 sur les phénomènes électro-dynamiques. (Voir aussi les travaux de Zöllner, etc.).

Cet article peut se résumer ainsi:

a) observations sur les lois fondamentales électro-dynamiques;
b) identité des parties mobiles des corps dont le mouvement constitue la chaleur, le magnétisme et le galvanisme;
c) identité de la force vive produite par la force électro-motrice avec la chaleur développée dans le conducteur par le courant;
d) mouvement de l'électricité dans les conducteurs;
e) propagation en double sens de la chaleur dans les corps pondérables;
f) théorie de Kohlrausch sur la thermo-électricité;
g) résistance et maximum de l'intensité du courant;
h) distribution de l'électricité dans les conducteurs.

2. *Sur les phénomènes électro-dynamiques*, par F. Zöllner. (Poggendorff Ann., vol. CLIV, page 322).

Helmholtz a cherché à remplacer la loi d'Ampère par une autre loi qu'il désigne sous le nom de loi des potentielles. Zöllner croit cette loi défectueuse au moins en ce qui concerne son application aux phénomènes de la rotation d'un conducteur électrique autour d'un aimant. Il appuie cette opinion par les résultats de nombreuses expériences faites avec des conducteurs solides et liquides que le courant électrique qui les traverse entraîne dans un mouvement rotatoire autour d'un centre magnétique.

3. *Sur quelques objections faites contre la loi de Weber*, par C. Neumann. (Poggendorff Ann., vol. CLV, page 211).

C'est la discussion des objections faites à la loi électro-dynamique de Weber par Tais, Thompson et Helmholtz. L'auteur arrive au même résultat que Zöllner (voir art. précédent) à savoir: que la théorie de Weber est encore aujourd'hui la seule qui soit en rapport avec les faits expérimentals.

4. *Sur les constantes diélectriques des liquides*, par P. Silow. (Poggendorff Ann., vol. CLVI, page 389).

Examen expérimental de la théorie de Helmholtz: « si deux masses électriques E et E' se trouvent dans un milieu diélectrique dont la constante diélectrique est D, ils s'influencent alors comme $\frac{E}{\sqrt{D}}$ et $\frac{E'}{\sqrt{D}}$ le feraient dans l'air ».

5. *Réfutations de deux objections faites contre la théorie unitaire de l'électricité*, par E. Edlund. (Poggendorff Ann., vol. CLVI, page 590).

L'auteur défend sa théorie contre les objections faites par Messieurs C. Neumann et G. Baumgartner d'après lesquelles l'induction unipolaire ne pourrait s'expliquer que par l'existence de deux fluides électriques, tandis

...er granulé ou en faisceaux.

...the general... himself landed in the mists... inducible" matter, "equipotent," "electrogen... and the like. Why "insulators" again have to | coating...

38

échantillons dont la résistance spécifique variait entre 75 et 4000 fois celle du mercure.

3. Sur la résistance électro-chimique de l'aluminium, par E. Ducretet. (Comptes-rendus, tome LXXX, p. 280.)

Si un voltamètre a pour électrodes une plaque de platine et une d'aluminium, le courant passe facilement quand l'aluminium est l'électrode négative, tandis qu'il devient très-faible dans le sens inverse. Le voltamètre est ainsi en quelque sorte une soupape électrique qui laisse passer l'électricité dans un sens, mais pas dans l'autre.

4. Sur le passage de l'électricité dans les électrolytes, par E. Budde (Poggendorff, Annalen, vol. CLVI, page 618).

Développement de la théorie de la propagation de l'électricité dans les électrolytes.

5. Résistances et leur mesure, par H.-R. Kempe (The Telegraphic Journal, vol. III, pages 158 et 222.)

Quoique d'une valeur et d'une application générales, les développements de cet article se rapportent plus particulièrement aux câbles.

ÉLECTRO-MAGNÉTISME ET MAGNÉTO-ÉLECTRICITÉ.

1. Note sur le magnétisme, par Th. du Moncel. (Comptes-rendus tome LXXX, page 532.)

Il s'agit des électro-aimants à noyaux tubulaires au lieu de cylindres massifs. Ces aimants atteignent la même force que les derniers, si le pôle est bouché ou couvert d'une plaque en fer; mais ils présentent quelques avantages vis-à-vis des cylindres massifs, en ce sens que la désaimantation s'opère plus vite et plus complètement; il reste après l'aimantation moins de magnétisme rémanent.

2. Note sur les électro-aimants tubulaires à noyaux multiples; par J. Camacho et Th. du Moncel. (Comptes-rendus tome LXXX, pag. 312 et 1572, et tome LXXXI, page 17.)

Ces électro-aimants ont été construits pour la première fois par M. Camacho. Les expériences faites par M. du Moncel se rapportent à un électro-aimant à 3 noyaux tubulaires de 6,5 centimètres de longueur et 2 millimètres d'épaisseur. Au centre, il y a un noyau solide de 6 mm. de diamètre. Le tube extérieur a un diamètre de 3 cm. Chaque noyau intérieur est revêtu de deux couches de l'hélice magnétisante, le noyau extérieur de cinq. Quand le courant passe par toutes les hélices, le magnétisme est beaucoup plus intense qu'il ne le serait si la masse du fer des noyaux formait un seul noyau solide. Quand le courant ne parcourt que l'hélice d'un seul noyau, les autres noyaux deviennent aussi très-faiblement magnétiques, les noyaux intérieurs avec des pôles du même nom, les noyaux extérieurs avec des pôles de nom contraire. Quand les noyaux sont munis de semelles ou de bagues en fer qui remplissent le vide aux pôles entre les différents noyaux, l'effet magnétique est toujours amoindri. Pour atteindre le maximum de force magnétique, il faut par conséquent laisser les pôles ouverts de façon qu'ils présentent des anneaux concentriques.

3. Sur les courants d'induction produits dans les fils télégraphiques, par M. Lagarde. (Ann. tél. tome II, page 285).

Si deux fils télégraphiques sont posés sur les mêmes poteaux, toujours parallèlement et à grande distance, le courant d'un fil produit des courants d'induction dans l'autre fil. L'appareil Morse n'est pas assez sensible pour accuser l'existence de ces courants, mais il n'en est pas de même de l'appareil Hughes. Sur les câbles souterrains, où les âmes sont beaucoup plus rapprochées l'une de l'autre (distance seulement 8 mm.), ces courants d'induction peuvent même être observés à des distances ne dépassant pas quelques kilomètres. L'auteur a fait des expériences sur un câble entre Paris et Juvisy et sur des fils aériens entre Paris et Mâcon et entre Lyon et Marseille.

4. De l'influence du magnétisme sur l'extra-courant, par Trève. (Comptes-rendus tome LXXX, page 1597.)

Quand on produit dans un œuf électrique un extra-courant, la température à l'intérieur de l'œuf augmente de quelques degrés et la pression atmosphérique de 25 à 30 centimètres (en employant 15 éléments Bunsen); mais si l'œuf est placé entre deux pôles d'un électro-aimant puissant, cette élévation de température et de pression atmosphérique est beaucoup moindre.

5. Phénomènes magnéto-chimiques produits au sein des gaz raréfiés dans des tubes de Geissler, illuminés à l'aide de courants induits; par J. Chautard. (Comptes-rendus tome LXXXI, page 75.)

Compte-rendu d'expériences sur la séparation des éléments de différents corps composés. Les changements chimiques se manifestent par les variations de teinte du tube, ainsi que par l'apparition de raies spéciales.

6. Influence de matières diélectriques sur les courants d'induction; d'après J.-J. Muller par A. Kleiner. (Poggendorf, Annales, vol. CLVI, page 564.)

Comme une masse de fer à l'intérieur d'une bobine d'induction augmente le courant d'induction, mais qu'en l'enveloppant sous forme de cylindre, elle affaiblit ce même courant, il y avait lieu de présumer que des matières électriques, telles que le soufre ou la paraffine, produiraient dans les mêmes conditions des effets contraires. Le professeur Muller dont la mort a interrompu les expériences, a pu obtenir des résultats de nature à faire penser que cette thèse sera probablement vérifiée par les faits. Il faut observer toutefois que, s'il y a une influence de la part des matières diélectriques, elle est extrêmement faible.

7. Décomposition d'un électrolyte par l'induction électro-magnétique; par J.-A. Fleming. (Electrical News, vol. I, page 124.)

On sait que des courants électriques se produisent dans un conducteur solide quand il se meut dans un champ magnétique. Est-ce aussi le cas pour un électrolyte et dans l'affirmative l'électrolyse aura-t-elle lieu? L'auteur a fait couler dans des tubes en verre de l'acide sulphurique dilué entre deux pôles d'un électro-aimant puissant et il a constaté qu'un courant traverse le liquide perpendiculairement à la ligne qui joint les deux pôles. Le courant de polarisation a montré, en outre, que l'électrolyte est décomposé par ce courant.

(A suivre.)

THEORIES OF ELECTRICITY.

[13134.]—The letters which have appeared in your last three or four issues on the "Earth as a Reservoir," &c., show how little the mechanical theory of electricity is understood, even among those who have a very considerable knowledge of electrical facts. Your correspondent, "Sigma," both in his letters and in his invaluable work, evinces a perfect mastery of the mechanical theory; but, with all due respect to him, I do not think his work makes the theory clear to the beginner. Prof. Felice Marco, of Turin, is perhaps the only one who has taken the trouble to explain every known phenomenon by this theory; his latest contribution in this direction being a pamphlet on the zodiacal light. If it meets your views I shall be happy to give a series of translations from the Italian physicist's excellent work, "Teoria Meccanica dell' Elettricità." I may state, however, in reference more especially to letters 12993 and 13037, that the earth has no more right to the denomination "reservoir of electricity" than it has to be called reservoir of force when a ball thrown on its surface bounces up again. A. F. J.

SOCIETY OF TELEGRAPH ENGINEERS.

An ordinary general meeting of this society was held in January at the Institution of Civil Engineers, Great George Street, Westminster, London. The first business done was to pass a hearty vote of thanks to Mr. C. W. Walker, F.R.S., the retiring President of the Society, under whose auspices, it was said, it had gone on increasing in numbers and importance.

Professor Abel, F.R.S., the President for the ensuing year, then proceeded to deliver his inaugural address, which he commenced by observing that the prominent position to which the Society had attained among the associations in applied science must in a great measure be ascribed to the wisdom which had hitherto been exercised by its members in the selection of the men to whom had been intrusted the management of its affairs. He, however, who had contributed nothing to the pure science of electricity or to the advancement of telegraphy could hardly have hoped in the wildest flight of his imagination to succeed to a position which had been occupied by such men as Siemens, Scudamore, Thompson, Clark, and Walker, and he could only attribute his selection for the post of President of the Society to a desire on the part of its members to testify their recognition of the special importance of chemical science in its application to the work of the telegraph engineer. So strong was his conviction that it was to that consideration he owed the privilege of addressing them that evening that he felt confident he was only rightly interpreting their wishes in endeavoring to illustrate some of the principal directions in which chemical science bore importantly upon that work. And there could, he thought, be no better illustration of the value of combining chemical with electrical research than that which was furnished by the investigations of the late Dr. Matthiessen, relating to the causes of the differences in electrical conductivity exhibited by different kinds of commercial copper. By a systematic series of experiments, that accomplished chemist ascertained, in the first instance, the influence exerted upon the conducting power of pure copper by the principal metalloids and metals known to be naturally associated with it, and afterwards determined the conducting powers of important varieties of commercial copper. The conducting power of pure copper he found not to be susceptible of increase by alloying the metal with any other substance, while certain non-metallic elements occurring as very frequent impurities in the copper of commerce exercised a very prejudicial influence on its conducting power. Thus, the conductivity of pure galvanoplastic copper being fixed at 100, the addition of only traces of arsenic to the metal reduced its conductivity to 60. Some further experiments of Matthiessen elucidated the cause of the good effects produced upon the working qualities of refined copper by the addition of small quantities of lead, which operated in removing some impurities which were detrimental to its toughness and ductility. A sample of pure copper after fusion in contact with air had a conductivity of only 87·25; 0·1 per cent. of lead was added to the metal, the two being fused together in a current of carbonic acid, and by that treatment conductivity was raised to 93. The analysis, Professor Abel went on to say, which Dr. Matthiessen made of a series of commercial coppers, the conductivity of which ranged from 14 to 92, and of six specimens of the core of the Gibraltar cable, the conductivity of which ranged from 67·4 to 90·7, afforded interesting confirmation of the results of his investigations upon the conductivity of pure copper, and contributed in a very important degree to indicate to the wire manufacturer the sources whence he should obtain, or the conditions as regarded purity to be fulfilled, in preparing metal of a quality best suited to the purposes of a telegraph engineer. But while chemical science had unquestionably facilitated the selection of fitting materials for the conductors of cables, it had also been usefully applied in connection with the substances available as dielectrics in cable manufacture, and it was in that direction especially that important benefits from the labors of the chemist were to be looked for in the future. The Submarine Telegraph Committee, the result of whose inquiry was published in a valuable Blue-book in 1861, requested Professor W. A. Miller to investigate the causes of the decay of gutta-percha and india rubber, and he arrived at the same conclusion as that to which Professor Hoffman had previously come—that decay was due to oxidation, through atmospheric influence, of the gum, which became transformed to a more or less considerable extent into a brittle resinous substance. Professor Miller also pointed out that an intermittent exposure of moisture, particularly if solar light had access, was rapidly destructive of gutta-percha, while if kept continually immersed in water it remained practically unchanged for indefinite periods. Now, the mechanical processes of preparation of gutta-percha had doubtless undergone considerable improvements since the date of the Marine Telegraph Committee's Report, but, judging by the results of some chemical examinations which he himself had recently made of samples of new gutta-percha, it did not appear to him that there was much improvement in the quality of the material as indicated by its chemical composition, for although a high-priced sample contained just below 13 per cent. of resin, it contained even more inclosed water than two somewhat lower priced samples, while in several samples offered at about the same price, by different well-known makers, the resin ranged from 20 to 27·5 per cent., and the water from 8 to 12 per cent. Professor Abel, after dwelling at length upon this part of his subject, went on to give some illustrations from his own experience of the imperfect nature of existing knowledge regarding the chemical and other conditions to be fulfilled in the application of vulcanizing processes to the preparation of telegraph cables. It was scarcely necessary, he added, to impress upon the Society the importance of the application of chemical research to the more complete study of the causes of the defects in the dielectrics at present in use, and to the production of insulating preparations suitable for cable covering which should possess the chemical as well as physical qualities essential to permanence. The efforts which had been made from time to time to produce new insulators or to improve the existing ones might be said to have served until lately chiefly to clear the ground for future experiments; but there was one direction in which, after repeated efforts, an important success appeared to have been achieved. One of the most absolutely permanent materials of organic origin was the solid product of the distillation of peat and of certain descriptions of coal or bituminous minerals which also existed in many varieties of petroleum or mineral oils, and which was known as paraffin or as fossil-wax. That substance, which during the past 30 years had passed from the obscure position of a chemical curiosity to the foremost rank among important chemical products, thanks to the practical development of the results of pure chemical research, was possessed of high insulating power, and had consequently received some useful applic-

39

simple costume of the goddesses, passes before the car of Apollo, the god of the sun, while Science observes the phenomenon on the earth and records the results. The legend is the composition of a member of the Academy of Inscriptions. On the obverse of the medal is the following Inscription :—

INSTITUT DE FRANCE

THE EFFECT OF INAUDIBLE VIBRATIONS UPON SENSITIVE FLAMES

DURING a recent visit to Birmingham my friend and host, Mr. Lawson Tait, showed me some interesting experiments with one of Mr. Galton's whistles, capable of yielding vibrations beyond the limit of hearing. This led to the suggestion of trying a sensitive flame with these whistles, and in fulfilment of my promise to select and send to Mr. Tait a burner sensitive to very high notes, I was yesterday led to make the following experiment, the result of which is, I believe, new, and I think sufficiently interesting to put on record. A sensitive flame was obtained just two feet high when undisturbed, but shrinking down to seven inches under the influence of the feeblest hiss or the clink of two coins. Adjusting the Galton whistle, which Mr. Tait lent me, so as to yield its lowest note, little effect was produced on the flame; a shrill dog-whistle produced a slight forking of the flame, but that was all. Raising the pitch of the Galton whistle, the flame became more and more agitated, until, when I had nearly reached the upper limit of audibility of my left ear, and had gone quite beyond the limit of my right ear, the flame was still more violently affected. Raising the pitch still higher, until I quite ceased to hear any sound, and

vibration number of these high notes, and thus with greater exactitude fix the upper limit of hearing.

The flame giving the effect here described was produced by coal gas contained in a holder under a pressure of ten inches of water, and issuing from a steatite jet having a circular orifice 0·04 inch in diameter.[1]

W. F. BARRETT

SOUND-VIBRATIONS OF SOAP-FILM MEMBRANES

THE vibration-forms of membranes agitated by their fundamental and upper tones, have usually been studied by means of thin bladder or india-rubber stretched on a ring or frame (see Helmholtz "Sensations of Tone," chaps. iii. and v.; Pisko, "Die Neueren Apparate der Akustik," p. 75). While I was lately trying with Mr. R. Knight the capabilities of various membranes of taking impressions from vocal sounds for phonautographic purposes, the idea occurred of using soap-film. This was at once carried into effect by dipping the end of a lamp-chimney into some soap-solution, strengthened in the usual way with glycerine and a little gelatine. On singing near the open end of the chimney, the series of forms belonging to the various notes became plainly visible, those produced by the upper tones being as it were engine-turned in their complex symmetry, in a way to which the sand-lines on so coarse a material as caoutchouc can bear no comparison. To exhibit these forms at a popular lecture here last night, the light of an oxyhydrogen magic lantern was simply reflected off the vibrating film upon the screen in a disc of some three feet in diameter, so as to show its patterns on a large scale when set in movement by talking, singing, and playing a cornet in its neighbourhood. The effects were of singular clearness and beauty. To lecturers who may use this new and easy means of making the more complex sound-vibrations appreciable by the eye, I would mention that by slightly thinning the soap-solution, and adding a few drops of ammonia, they may obtain a film more free from interference-colours, so as to display the vibration-figures on an almost clear ground. But if this is done, the thicker mixture should be used afterwards, for the gorgeous scenic effect of the masses of prismatic colour whirled hither and thither by the musical vibrations.

THE OTHEOSCOPE[2]

I COMMUNICATED to the Royal Society in November last, an account of some radiometers which I had made with the object of putting to experimental proof the "molecular pressure" theory of the repulsion resulting from radiation. Continuing these researches I have constructed other instruments, in which a movable fly is caused to rotate by the molecular pressure generated on fixed parts of the apparatus.

In the radiometer, the surface which produces the molecular disturbance is mounted on a fly, and is driven backwards by the excess of pressure between it and the sides of the containing vessel. Regarding the radiometer as a heat-engine, it is seen to be imperfect in many respects. The black or driving surface, corresponding to the heater of the engine, being also part of the moving fly, is restricted as to weight, material, and area of surface. It must be of the lightest possible construction, or

[1] The conditions necessary for obtaining the utmost sensitiveness of the flame are described in an article I published on the subject in the *Popular Science Review* for April, 1867.

Velocity of Electricity.

Dr. Sabine has devised a method of measuring the contour of electric waves passing through telegraph lines. It is probable that in this sense alone electricity may be said to have a velocity. The early experiments on the time elapsing, between starting electricity into one end of a conductor and receiving it at the other end, gave totally contradictory results. This interval would depend on the electromotive force employed, the resistance and capacity of the conductor, and the sensitiveness of the receiving instrument. It would therefore by no means be proportionate to the length. By the following method the electrical condition of any point of the line may be examined quantitatively at intervals of 0·001 of a second or less after starting the electric impulse. It thus becomes possible to measure the form and speed of a wave. Suppose one end, A, of a conductor, A B, is placed to earth, and that the other, B, is connected with one pole of a battery whose second pole is put to earth. Then any point of the conductor, as C, will assume a potential which will be proportional to the resistance of A C. This potential may be measured by connecting C for an instant with a condenser or accumulator, and then discharging the latter through a delicate galvanometer. When the circuit is first closed, a minute interval of time is required before C will attain its full potential measurements made of the relation of these quantities, showing the form of the electric wave passing the point, C. The only mechanical difficulty is to construct a chronograph which will allow C to be connected with the condenser, a small but accurately determined time after A is connected with the battery. A heavy wheel of brass is set in motion by a steel spring so that it shall revolve exactly twice a second. The interval through which the spring acts being always the same, a nearly constant velocity is always imparted. The disk is divided into 500 equal parts. A movable index serves to regulate the angle through which

through the exhaust pipe. The exhaust steam itself lowers in temperature as its pressure decreases, and the live steam on the back of the valve is comparatively constant in temperature: as a result, then, the valve is continually changing in form from the expansion due to the high temperature of the exhaust steam during the early part, and the lower temperature during the latter part, of the exhaust. Now comes another and more important question, and that is: How far will the spring of the valve, from the pressure of the steam upon its back, affect the fit to its seat, and will it so spring as to permit of a fine film of steam finding its way beneath the wings of the valve, thus relieving, to a certain extent, the amount of its pressure to its seat?

If we take a pair of the plates shown in Fig. 1, and get them so closely together that it requires, say, 340 lbs., to slide one upon the other, and then take hold of the plates by ... we can pull them

THE LAWS OF THE PASSAGE OF ELECTRICITY THROUGH GASES.

77

A PAPER by M. G. Wiedemann on this subject is published in *Pogg. Annal.* An abstract of it will be found in the December number of the *Journal de Physique.* The apparatus employed by M. Wiedemann was a Holtz machine, one of the conductors of which was in connection with the earth. The other communicated with one of the electrodes between which the discharge took place, the other electrode being connected with the earth by a circuit of which a galvanometer formed a part. Without going into the facts observed by M. Wiedemann, we may state some of the conclusions which he drew from them: The discharge, or rather the series of discharges, taking place between the two electrodes cannot be assimilated to an electric current; the more or less rarefied air or vapors offer no resistance in the electrodynamic sense of this word. A certain charge is necessary on each electrode before discharge can take place. This limit attained, the gaseous molecules are driven far from the electrodes, carrying with them the electricity with which they are charged. The differences noticed by observers in the luminous appearances at the two electrodes, as also the differences in the intensity and number of discharges between two electrodes of different forms, when the direction of the current is reversed, are attributed by M. Wiedemann to the fundamental fact that the positive discharge only commences when the potential of the positive electrode has attained a value superior to that for which the negative discharge takes place.—*Academy.*

77

Depolarization.—M. Lippmann.—The depolarizing power of certain salts has long been known. The first constant current battery constructed in 1829 by M. Becquerel depends on the use of copper sulphate, while zinc and calcium sulphates have been utilized by MM. Du Bois-Reymond and J. Regnault for the construction of impolarizable electrodes and of constant elements. This property, however, has not been studied. The author's experiments reveal an essential condition of the phenomenon. In order that an electrode may be depolarized it must be formed of the metal which is contained in the solution. Thus copper is the only metal which is depolarized in copper sulphate, while gold, silver, and platinum are polarized in this solution. On the other hand, copper is polarized in zinc and cobalt sulphates, etc. A salt depolarizes only its own metal. This principle may be applied to the detection of a metal in a solution. Taking, for example, copper: if a wire of this metal be plunged in a solution under examination, and taken as the negative electrode of a feeble current, it will not be polarized if the liquid contains 1-5000 of copper sulphate. The presence of copper may thus be detected in a mixture of metallic salts. With a silver wire silver may be detected in like manner.

Diamagnetism of Condensed Hydrogen.—R. Blondlot.—Graham had found hydrogenium-palladium more magnetic than palladium. Wiedemann ascribes this result to iron present as an impurity in Graham's palladium and reduced by the hydrogen. Blondlot agrees with Wiedemann, and finds that condensed hydrogen is powerfully diamagnetic. 77

ELECTRICITY AND THE EARTH.

[12926.]—"No Sirrah" (12915, p. 440) considers I am wrong in objecting to the commonly taught doctrine that electricity is pumped out of the earth by friction machines, and runs away into it again like waste water into the drains. He brings up the old statement that, "after a few turns, we cannot get any more sparks, the quantity of positive electricity in the rubber having been exhausted." Now, this statement, though made in all the paste and scissors "textbooks," is absolutely a falsehood as to the fact, and a ridiculous absurdity as to the explanation, and the mischief of it is that it results in false conceptions of the nature of electricity, and of its actions, and necessitates a whole series of equally erroneous corollaries as to charge, bound, and dissimulated electricity, &c.

If "No Sirrah," and other believers in these old tales, will read my articles in Vol. X., "Electricity: its Theory, Sources, and Applications," or the second chapter of my book of the same title, they will find these notions fully dealt with, and their absurdity exposed. They date from the early days of electrical discovery, when its frictional sources were alone known, and when people had a fashion of inventing "a fluid" at pleasure, or devising some kind of explanation of facts before they had any extended knowledge of the facts; but all this "earth" elaboration, however it may be adapted to mere frictional electricity, is a mere incumbrance directly we deal with electricity derived from any other source, and the necessity of making later knowledge agree in some degree with the old infantile theories produces confusion.

It is not true that it is necessary to connect either the rubber of the machine or the sole of the electrophorus to "earth," as the textbooks say. We can get as many sparks as we please, and keep them going for years if we please, with the apparatus as perfectly insulated as possible—that is to say, without either a means of drawing positive electricity from the earth, or a drain pipe to run off the negative to the earth, both of which the old theory (or any theory which treats "earth" as an electrical source) pronounces absolutely essential.

How, then, does the erroneous notion arise? Very simply. A chain is dropped from the rubber to the floor, or somewhere where it will find some conducting body, and without this but little electricity can be obtained. But let us try to bottle off a little of the fluid we suppose we pump up through this chain, and put it into a Leyden jar; we find we must drop another chain from this also to earth, and a new explanation is devised which constitutes this into a drain pipe for the negative electricity to run off by. It never seems to have occurred to the inventors of this complex notion that these two chains, by both being connected to earth, were simply connected to each other; but in actual fact, if we insulate all the apparatus perfectly, and just join these two conductors, we get all the effects without the "earth" having anything to do with the matter, so proving that it is not the source of the electricity.

But this does not appear so evident in the seemingly simpler case of charging an insulated surface with positive electricity, requiring only one chain to earth. But the erroneous theory has shut the eyes of observers to the facts, and led to nearly universal misconception as to what occurs in this case. No such charge of positive electricity really occurs. The phenomena are exactly identical with the case of the Leyden jar. Whatever positive electricity is found on the prime conductor or surfaces connected to it, an equal quantity of negative electricity is to be found on surrounding surfaces. The brass chain forms no connection to earth, but it does form a connection to these surrounding surfaces. It does not act as conduit for positive electricity (from the earth as a source) to be packed upon bodies to be charged, but it does connect the opposite side of the insulating medium—*i.e.*, the air of the room, so as to permit an electric charge to accumulate in that air, just as under other circumstances it does in the glass of the Leyden jar.

July 77 SIGMA.

43

ELECTRICAL VORTICES.

From observations made on the escape of steam from kettles and railway engines, and of smoke from tobacco pipes and cannon, I was led to believe that many of the evolutions performed by the discharged vapors arose from their being in a different electric condition to that of the surrounding media, that they were in a spheroidal state, that the rings and various forms of rotation they assumed were due to this condition, and that the particles of vapor and smoke were involved in electric vortices.

Mr. Robert Hunt's experiments on the influence of magnetism on molecular arrangement* favor this view; and, as they are important and may not be readily accessible to some of our readers, the following extract may perhaps be admissible:

"12. A plate of copper, with an edging of wax was placed on the electro-magnet, over it a very weak solution of nitrate of silver was quickly poured; the plate immediately blackened from decomposition of the silver salt by the copper. In about a minute the finely-divided silver arranged itself into curves which were after a few minutes again destroyed. By using a sheet of chemically pure copper obtained by electrotype deposit I found a permanent impression of these curves could be obtained owing to the oxidation of the copper along the spaces, which the finely-divided silver, when distributed in curved lines, did not occupy.

"13. A plate of hard copper, such as is used by engravers, was placed in precisely the same circumstances and covered with a tolerably strong solution of nitrate of silver. It was left in contact with the electro-magnet for a night. On washing off the deposit of silver which covered it, it was found that the acid of the silver salt had bitten deeply into the plate over an oval space around the poles, leaving a small space between them quite bright. The copper over this etched space was covered with an immense number of minute holes, and, beyond this, the oxidation of the surface had proceeded in curved lines. We thus have permanent evidence of the influence of magnetic force in determining chemical action.

"14. Into one of the glass troughs before named—a plate of glass with an edge of clay—placed on the electro-magnet, a weak solution of sulphate of silver was poured, and into this an equally weak solution of sulphate of iron. In about five minutes precipitation of silver commenced. This precipitate arranged itself over the glass in curves from and around the poles in the same manner as it distributed itself over the copper plate. In a short time precipitation increasing, two curious curved spaces were formed by the fine deposit, proceeding from one pole toward the other in opposite directions, increasing in width as they proceeded, until they were abruptly checked at little distance from the poles towards which they were directed, these spaces being very distinct from the first formed curved lines.

* Philosophical Magazine, third series, Vol. XXVIII., page 1.

Thus far as regards the effects of electro-magnetism on chemical action in progress. But there seemed something wanting between it and the effects of the poles of an electro-magnet on loose particles of matter not immediately involved in chemical action. While I was studying a means for supplying this want, M. Gaston Planté's very simple and ingenious experiments were made known, which meet what is required. It is unnecessary to repeat them here, as they have been already noticed in these columns.*

These experiments indicate most distinctly the existence of electrical vortices. In M. Planté's experiment the fluid passing from the electrode involves the metallic particles and renders the vortex visible. The explanation I gave twenty-seven years ago of the behavior of the electric fluid when passing along a wire† shows that it arises from the latitudinal and longitudinal action of the fluid upon itself, owing to which it moves corkscrew fashion, the principle involved being that of two forces propelling a body on the diagonal of the direction of those forces. The paper referred to was an explanation of the cause of the magnetic needle assuming its peculiar position in Ampère's experiments when a current is passed along a wire. This paper would not admit of being abstracted, and would seem too long to insert here. But M. Planté's experiments confirm what was there said, and show the current passing off into loose and liquid materials, continuing, as far as these can hold together, the vortex established on the wire.

This is very noticeable when he illustrates the formation of waterspouts, producing in a mixture of salt and water similar gyrations to those witnessed in that meteoric phenomenon, and showing the tendency of the liquid to rise in the vortex. The direction of gyration in these experiments is also found to agree with that of waterspouts in nature, the reversal of the experimental electric current changing the direction of gyration, as waterspouts revolve in opposite directions in two hemispheres, which M. Planté considers may be attributed to the flow of the electric fluid under the magnetic influence of the globe.‡

Another form of vortex appears in M. Planté's experiments. The immersion of the positive wire into a liquid conductor, such as salt water, determines the aggregation of the aqueous molecules about the electrode in the form of a luminous spheroid in consequence of a double simultaneous effect of flowing and suction—*d'écoulement et d'aspiration*—"or of transport in two directions that seems peculiar to the electric fluid."§

The whole universe develops vortices or centres of force *en rapport* with electricity. Amongst animals it appears in the ganglions and other nerve centres; in the vegetable world in the deposition of cells, in the roots, in the joints, the corolla, and the fructification; and in the inorganic world in every centre of chemical change; in the planets, in the solar system, in the Milky Way, and those still more distinct centres, the casual messengers from which occasionally visit our system.—JOHN J. LAKE, in *English Mechanic.*

176

ELECTRICITY.—To "Sigma." 77

[13216.]—Most willingly do I accept your gauntlet (let. 13169), and if I have departed from the original question—of whether electricity is or is not an entity—the fault, if any, I think, rests not with me. But let us now proceed to business, begin at the beginning, and taking facts in their order of date I will give a detail of the boiler experiment.

My authority has identified electricity with cold, or cold with electricity, and by letter of the 10th August, 1845, to determine the effect of electricity on red-hot iron, he solicited of the directors of the Polytechnic Institution his being allowed to put two bars of iron into the furnace of the hydro-electrical boiler, and when red hot to insulate them at a short distance from the boiler, "but so connect one of them with the boiler and the ground so that the fluid in its passage to the boiler shall pass through the bars." On his arrival at the theatre of the institution, where were Dr. Bachoffner and three or four other gentlemen standing among the benches, he was told by the doctor: "Mr. ——, you are altogether in error; the electricity does not go to the boiler, but only comes from it." "What, doctor," was the reply; "do you mean to say that the electricity that flows from the boiler with the steam has not previously gone to the boiler?" "Yes, certainly I do." After a minute or so of reflection, the doctor was requested to put the machine into action, and the request not being complied with, it was repeated, which produced the desired effect, when my authority, taking off his hat, notwithstanding the admonitions of the attendants, gradually approached the boiler, head foremost, until a vivid flash passed from his forehead to the boiler. Assuming again the upright position, he turned to the doctor and his friends, and having passed three or more flashes, he asked whether they were to or from the boiler, it being evident that, if the latter, he would not now be alive to tell the tale. Obviously, whatever may have been the idea of the doctor and his friends, the attendants anticipated fatal results, or that the flow of the electricity would have been from the boiler; and assuredly you, as an electrician, cannot require to be told "what the flashes of electricity reported prove against the received ideas that the electricity is produced by friction in the hydro-electric apparatus." That the electricity to the boiler was caused by the rushing out of the high-pressure steam from the boiler is unquestionable; but its being "produced" or generated is quite another matter. What may have been Dr. Bachoffner's thoughts I am unable to say, since he did not express them; but I think that, if inquiry be made, it will be found that the boiler ceased to be, very shortly, if not immediately, after the demonstration.

Fact 28, detailed in my letter 13011, p. 515—the flow or passage of the "intense cold" of a freezing mixture through the finest of copper wires to a hot solution of alum—is one of the subjects of the paper to Professor Faraday, and apparently escaped your notice. In that experiment there can be no friction, and I certainly should like to know what else than the electricity, "intense cold" of the decrystallisation of the ice and salt, is the cause of the crystallisation of the alum; and what it is that the rain of a heavy shower brings down that produces a similar effect. Professor Faraday, by letter of the 20th December, 1848, replied:—"I am obliged to you for the copy of the papers, and have looked them hastily through. I cannot undertake to do more, for I can hardly find time and strength to pursue my own views. You must be content to do as other philosophers do—form your own judgment, give it to the world, and then leave others to adopt it or not, according to their opinion of its value, or their ability to understand it. It often happens to me to be, as I think, misunderstood on very important points; but, having put them on record, I do not think that I have any right to press them, because, after all, I may be wrong. What I practise myself is, of course, that which I should recommend to you. I return the M.S. because, as there is a good deal of it, it may save you some trouble." No doubt you could write that reply more tersely than "gentle Faraday" would have found words for; but William Henry Weekes, who, as an electrician, can be no stranger to you, stated, by letter of the 29th February, 1849:—"If I have retained your papers longer than perhaps I ought, it is because they have interested me, especially your 'statements' comparing your own views and the doctrines of the schools. Stick to your 'electrical condition.' I have well considered all, and my conviction is unchanged as well as unchangeable. Surely you will ere long bring your guns to bear direct on the enemy."

My authority, I should tell you, on account of his principles, duly went through the ordeal of persecution, and one of no small magnitude, "gentle Faraday" notwithstanding. And now as to "Heat and Motion." I should like to know how you interpret the fact that, if one end of a bar of steel, say, 30in. long, be firmly held against a revolving emery-wheel, the other end of the bar burns the skin of the hand grasping it? Diffusion to the reconstitution of the atmosphere, decomposed by combustion, &c., is one of the "doctrines of the schools." A greater fallacy could not be, and the facts of decomposition of matter are the result of a protracted inquiry. But, for the present, let us deal with electricity, the hydro-electrical boiler, freezing mixture and crystallisation, and heat and motion, which latter, my authority contends, is purely electrical.

Scholasticus.

Has Electricity Weight? 78

Mallet has come forward with an experiment, apparently corroborative of that of Pinaul, described in the SCIENTIFIC AMERICAN of February 9, 1878, purporting to show that electricity has weight, or at least is under the influence of gravitation. He takes a straight copper wire three feet long, bends the ends downward, and suspends it at the middle to one of the arms of a delicate balance, while the bent ends dip in mercury. When the current of a moderately strong battery (say ten Grove cells) is passed through the wire by the intervention of the mercury, the arm to which the wire is attached, although accurately balanced by a counterpoise, will sensibly tend downward, notwithstanding the resistance produced by the buoyancy of the mercury. The conditions of the experiment, however, demonstrate that gravitation has nothing to do with it, and that it is merely due to the law of attraction of electric currents. These conditions are that the wire must be placed in an east and west direction, and that the current is sent in the same direction. According to Barlow's theory, electric currents travel in the earth's crust from east to west, and are the true cause of the direction of the compass needle, which, according to the law discovered by Oersted, places itself always at right angles to electric currents, while magnetic declination and variation are due to the direction and changes of these currents. Ampère discovered that currents passing in the same direction attract one another, and therefore that the subterranean earth currents exert an attractive effect on all conductors through which electric currents pass from east to west; hence the conducting wire goes down, while the electric action is added to the gravitation which was balanced by the counterpoise. But Ampère also discovered that electric currents running in opposite directions repel one another; *ergo*, when the electric current is passed through the suspended conducting wire from west to east, it must be repelled and driven upward against gravitation, and this deduction is fully verified by experiment, as in this case. The counterpoise goes down, and the balance may be made to oscillate by alternately reversing the currents; which proves that the theory based on the laws discovered by Barlow, Oersted, and Ampère, offers a correct explanation, without recourse to the novel hypothesis that electricity has weight.

ELECTRICITY. 77

[13244.]—"Scholasticus," letter 13216, p. 11, informs me for the first time what was the "original question" with him. I had thought that it was an inquiry into the causes of some chemical actions produced by high-pressure steam; I conceived that the electrical notions were but an offshoot of this, and I objected to confusing our minds by the endeavour to grasp, all at once, a whole collection of perfectly dissimilar and unconnected matters. I now learn that the original question—that is, in the mind of "Scholasticus"—was "whether electricity is or is not an entity." That question I debated pretty fully some years ago in a series of articles in these pages, now before the world in the shape of a book. The arguments I used no one has yet answered; when any one does so, I am quite ready to discuss the subject, but while those arguments, showing that electricity is not an entity but a form of molecular energy and motion, remain unattacked, I do not see that I can be expected to enter upon the examination of all kinds of ideas or facts which may or may not bear upon the subject.

Thus the reported experiments upon crystallisation did not "escape my notice;" I read them with interest, but I should not think of discussing them until I had myself witnessed them—not once but several times. Meanwhile, I have on hand many much more important experiments for which I cannot find time and power. I cannot accept the "authority" on which "Scholasticus" relies because, while I do not doubt his honesty, I have no reliance on his experimental faculty. I see in numerous other cases that he misreads facts, and therefore think it probable he has done so in this case. Many points would have to be considered: one glass may have been in a draught and cooled more quickly, or it may have been in a stronger light, and I see clearly that the observer would have been quite incapable of giving a thought to such matters because he was simply looking for facts which should confirm his ideas, and any difference whatever would be triumphantly adopted as being due to electricity.

As to the hydro-electric matter, no doubt it will surprise "Scholasticus" (who says, as an electrician, I cannot require to be told it) when I again ask what the reported flashes prove? It appears they proved nothing to Bachoffner, who witnessed them, and I cannot imagine what they are supposed to prove. I do not need to see that experiment because I know that the flash would occur, and why it would do so. The insolated boiler was in a negative state, and any object which approached it would be positive and would form part of a more or less extensive inductive circuit, and at proper distance would pass a spark. The boiler, in fact, plays precisely the part of the rubber of a friction machine. "Scholasticus" must pardon my saying that I do not approve of the spirit of the concluding remark on this topic. Bachoffner it seems did not express his thoughts, probably because he came to precisely the same conclusion as I have, and saw that his interlocutor was one of those men to whom it was useless to talk, because they raise such a mist in their own minds that they can see nothing but the vague figures reflected from the mist. But when it is hinted that "the boiler ceased to be, very shortly if not immediately after the demonstration," dishonesty is implied; it means that Bachoffner and others were convinced that they had given a misinterpretation of facts, and were not men enough to admit it. Now, the fact is, that the boiler has not ceased to be—it stands, I believe, to this day in the Polytechnic Hall—but it has ceased to have any interest. Like the enormous plate machine which stands there also, it served as an attractive and an amusing scientific illustration for a time, and then it was superseded by something else. The boiler was also a novelty, and, no doubt for a time, was expected to prove important, but as soon as it had been studied and was understood, its interest passed away. One circumstance alone suffices to show the fallacy of the ideas of "Scholasticus's" authority. With perfectly dry steam (electric steam) no electricity is generated; with steam partially condensed the boiler becomes negative, and the conductor charges with positive electricity, as does a friction machine with a glass plate. Now charge the steam with oil of turpentine, and the boiler becomes positive and the conductor negative, as in a machine with an ebonite plate. Would this be possible if the steam were really electric, or if the electricity were an entity coming to the steam from the earth, from the fuel, or from anywhere? If the electricity were really a something present in the steam, which, in fact, owed to it its energy, would the presence or absence of a few drops of a foreign liquid entirely change its character? It is easy enough to comprehend this when we recognise that electricity is simply energy guided by molecular polarity, and ready at any instant to resume the form of heat or mechanical motion.

Now, for the next fact of the heat generated in an iron bar, or rather through the iron bar; the interpretation involves no difficulty whatever. The end held against the emery wheel is subject to violent friction and becomes very hot, and this heat would only be slowly transmitted along the bar; but other effects would also arise. I think it quite likely that a current of high tension electricity would be set up, resulting in a series of discharges into the hand but whether this be so or not, a powerful tremor would be set up, resulting in a rapid series of blows delivered by the end of the bar held, and these would produce heat in the hand, though the bar itself remained cold, just as the hand is heated beyond endurance by drawing a cord rapidly through it. All this is the A B C of heat science, but what "Scholasticus" means by "diffusion to the reconstitution of the atmosphere, decomposed by combustion," &c., is a profound mystery to me. He seems to assume that these cabalistic phrases form part of the "doctrines of the schools," but I should like to learn from what textbook he extracted them. I am quite willing to agree with him that a greater fallacy could not be, although I do not see what "the facts of the decomposition of matter" have to do here.

Now, a few words as to "persecution." If a man sets himself against the world, the world laughs at him, and if he gets in its way kicks him out of it; what else can he expect? If a man with an active mind thinks he has discovered something new, and proceeds forthwith to tell every one else that they are fools, and he alone knows the truth, can he complain if they in return regard him as a conceited and wrong-headed man? Can he wonder even if this opinion of him results in damage to his interests, if those interests are in any way dependent upon the opinion people form of him? But it is folly to call this persecution; it is what any man ought to expect if he sets himself, either rightly or wrongly, against the stream of life; it is what any sensible man (who ventures to think his own thoughts and endeavours to modify accepted views) prepares himself to meet, and either to conquer or endure. But the paradoxers who very freely call every one else fools, and insist that they alone know the truth, who will persist in holding forth their half-understood facts and crude ideas, and will pay no attention to the work of other people, are generally very thin skinned themselves. When people laugh at them they begin to whine about persecution, and they think themselves dreadfully ill-used when people who know their subject and see through the absurdities presented to them refuse to go seriously over and over the ground of examining and refuting them in detail.

INFLUENCE OF HEAT UPON MAGNETISATION. 77

M. J. M. GAUGAIN.

M. Favé had pointed out that when a bar of steel is magnetised at about 350°, allowed to cool, and heated again, the quantity of magnetism augments, and may reach triple the value which it had preserved after cooling. M. Wiedemann maintains that a bar magnetised at an elevated temperature loses on cooling a part of its magnetism: it loses a further portion when heated again, but on cooling it resumes a part of what it had lost. The author believes that this contradiction is due to the circumstance that M. Wiedemann experimented only with bars heated to 100°, whilst M. Favé operated with bars magnetized at a far higher temperature.

ELECTRICITY. 77

[13688.]—WHEN I took the (perhaps unwise and needless) trouble of repeating the experiment in crystallisation, about which "Scholasticus" says so much, I endeavoured as much as possible to adopt his conditions. He now says (letter 13632, p. 289) that I have "reversed the order of things." Now, the fact is that the slight difference to which he refers, so far from reversing the order of things, would not make the smallest difference in the results. He says, "In neither of the solutions was there any wire, big or small," and yet he actually describes two wires as "bent over the tumbler, so as to just and barely touch the surface of the solution." Now, that "just touching" is the very point in which he fails, for he does it only in the one solution. An infinitesimal point of solid substance is enough to determine and modify crystallisation, as is well known in experiments with supersaturated solutions. My arrangement was practically the same, for I secured the wire to a bar crossing the tumbler, and inserted about ½in. of the wire, twisted up in a spiral, in the solution; but I did the same in both, and connected one only to the freezing solution. When I began I was pretty sure I was wasting my time, and that no kind of effect would be produced, and what I expected, that I found.

Here I finally dismiss that matter. If "Scholasticus" believes in it yet, he should carefully repeat his experiment, and see if he finds any effect; if he does, and will describe it, I will take the trouble to examine the matter; till then I regard the discovery as a mare's-nest, and will have nothing more to say to it.

"Scholasticus" seems to think that his lucubrations are like wine, and are to improve by keeping. He keeps on extracting and referring to papers he wrote in 1819, &c., and things he drew up for the Government, for Professor Faraday, and goodness knows who. But if those papers were rubbish when written, they are no less rubbish when quoted 30 years later, and the fact that they were written with the intention of pestering distinguished men with them, sheds no halo on their own merits. He now even quotes some unknown "S.," who appears to have had nothing better to do than to write 17 papers, apparently of about equal value, based upon the discoveries (!) of "Scholasticus," and, as he has contrived to mix up this "S." and "Sigma" in his paragraph, I feel it due to myself to say that "S." and "Sigma" are not the same—indeed, very much not so. In 1819 I was in Australia, using, it is true, my pen pretty freely; but, if it had happened to write about these discoveries I feel pretty sure "Scholasticus" would not have much cared to quote my remarks.

It is quite evident, from his own account, that "Scholasticus" has all his life been afflicted with a chronic mental diarrhoea. When he has obtained some intellectual food in the shape of ideas he has not been happy enough to digest them, and use them in building up a wholesome healthy mind. They seem to have always disagreed with him, and produced a desperate attack of cacoethes scribendi, which has rendered him a nuisance to every one to whom he approached. Some sharp caustic remedies applied to his diseased vanity in earlier days (and that remedy, efficient or not, would have been administered had he come under my hands in 1819) might have cured him, and made him happy and useful afterwards. As it is, the case is hopeless. I do not write with the least idea of convincing "Scholasticus;" he has for so many years fancied he was exploring the universe, while he was only peering about with his own little glimmer of a monochromatic lantern (rose tinted), that now real light would probably be too much for his mental eyesight. If I heed anything he says, what I say is really intended for the many readers, who may think that what he says, so distinctly and with so[me] words, may be really of some significance.

Now it seems that the unknown "S.," his apparent disciple of "Scholasticus," felt that the phrase "attraction of cohesion" has no meaning, and that the other phrase, "attraction of gravitation," might as well be gravitation of attraction. Other scientific terms, such as "energy," also have no meaning (that "Scholasticus" can discern), and "molecules" simply "convey an indefinite idea," according to his notions. Now, in fact, the two last do convey real conceptions, and the terms molecule and molecular are most rigidly exact and definite. Those I will not trouble about; but as to the attractions of cohesion and gravitation, I, and all men of science, are so far at one with the paradoxists that we also say they do not convey an intelligible idea. We know perfectly well that they convey no explanation (nor do heat, weight, &c.); they simply express the fact that such attractions exist; they do not define or explain the causes. Now "Scholasticus" steps in triumphantly and explains it all. He says all these things are visions—they do not exist, they are effects of a cause, and that cause is electricity. Well this is a great step; but, just one moment, before we take it please, what is electricity? Well, we are told it is cold, it is crystalline energy, it is this, that, and the other thing; it causes weight, it causes heat, it is everywhere, and does everything. But surely all this does not answer the question. The fact is, that electricity so used is merely another word without meaning, used to wrap up in one comprehensive but incomprehensible bundle all the other words which are condemned. Then "Scholasticus" pathetically exclaims, "this monotonous conclusion has not been tested—the experiment, simple as it is, is in abeyance." Go [on] "Scholasticus," and make it. SIGMA.

[31710.]—Electricity.—The querist evidently wants to do something impracticable. It would be absurd to try to work a magnet of the sort through 2 or 3 miles of wire. If to be done at all, it should be by a local battery and relays; and "Inquirer" cannot get the information he wants all ready cut and dried, but must learn something of the subject for himself.—SIGMA. 78

Electrical Experiment 78

THE inclosed letter gives an account of an experiment in which an electric current appears to be produced by the direct action of gravity, a result which, if clearly established, would be new and of considerable scientific interest.

In trying to repeat the experiment yesterday I observed a considerable deflexion of the galvanometer in the direction described by Mr. Pirani, but as this deflexion seemed to occur some seconds *after* the inversion of the tube, I examined the tube and found a small bubble of air working its way up through the solution, and as soon as it came to the top of the tube the deflexion occurred.

I have not yet had time to repeat the experiment without the bubble, but I mention this to show that care must be taken to secure that the electrolyte is homogeneous, and that it does not contain anything which will either sink to the bottom of the tube or float to the top, so as to act alternately on the two electrodes.

The fact that the deflexion continued for some time after the tube was placed horizontally seems to indicate the possibility of something which was shifted from end to end when the tube was inverted, but remained where it was when the tube was only laid on its side.

J. CLERK MAXWELL.

Cavendish Laboratory, Cambridge, December 28, 1877

"University of Melbourne, Oct. 30, 1877

"MY DEAR SIR,—On page 317 of vol. i. of your 'Electricity and Magnetism' it is pointed out that a greater electromotive force is required to produce a given current between zinc electrodes in a solution of sulphate of zinc when zinc is carried upwards than when it is carried downwards.

"I am not aware that it has been noticed that by the same reasoning as that by which the induction of currents is deduced from the force exerted between a circuit and a magnet and the existence of contact electromotive force from the Peltier effect, it follows that a current should exist if two zinc electrodes connected by a wire are immersed in a solution of sulphate of zinc, the direction of the current being (in the solution) from the upper to the lower electrode.

"I tested this a few days ago, using a glass tube eighteen inches long, filled with a saturated solution of sulphate of copper and closed by copper caps with wires attached.

"On connecting the wires with a very delicate Thomson's astatic galvanometer belonging to Prof. Halford, a very considerable deflection was produced (200 divisions) when the tube was held vertically, the direction of the deflection being reversed when the tube was reversed.

"If the tube, after being held vertically, was placed in a horizontal position, the deflection diminished, but several minutes elapsed before the index came to zero, which it eventually did. I cannot explain the time taken. I am now preparing to test the actual loss of weight of the upper electrode.

"I have the honour to be, Sir,

"Your obedient servant,

"F. J. PIRANI,

"Lecturer on Natural Philosophy and Logic, University of Melbourne.

"P.S.—If the phenomenon has not been noticed before I shall be obliged if you will kindly communicate it to NATURE.

"F. J. P."

ELECTRIC CURRENTS OF HIGH TENSION.

By M. GASTON PLANTE.

Comptes Rendus de l'Academie des Sciences.

FOR the purpose of studying the effects produced upon distilled water, I have augmented the tension of the current employed, by uniting 20 secondary batteries, each composed of 40 couples, making a total of 800 secondary couples, and giving a current about equal to that from 1200 Bunsen's elements.

When this current is caused to act upon distilled water, the effects observed by Mr. Grove with 500 of his nitric acid cells are reproduced, but much intensified. The positive electrode being previously plunged into distilled water, on bringing the negative platinum wire to the surface of the water and immediately removing it, a nearly spherical yellow flame is obtained, about two centimeters in diameter (Fig. 1). The platinum wire of two millimeters diameter quickly fuses and remains for some instants in a state of fusion to a height of 14 or 15 millimeters above the surface of the liquid. The flame is formed by incandescent rarefied air, by the vapor of the metal forming the electrode, and by the elements of the decomposed water vapor. Spectrum analysis clearly declares the presence, above all, of hydrogen.

If to avoid the fusion of the metal the intensity of the current is diminished by interposing a column of water in the circuit, the spark takes the form of a compact little globe of fire, from 8 to 10 mms. diameter (Fig. 2). Drawing away, slightly, the electrode, this globe takes an ovoid form; luminous blue points, continually varying in number and arranged in consecutive circles, appear on the surface of the water (Fig. 3). Rays of the same color soon start from the center and join these points (Fig. 4). At intervals the rays take up a gyratory motion, tracing out spirals, sometimes in one direction, sometimes in the opposite direction (Figs. 5 and 6). Sometimes the points and rays all disappear on one side, and various curves, formed by those which remain, are drawn on the surface of the liquid. Lastly, when the speed of the gyratory motion is increased, all the rays vanish, and only concentric blue rings are seen (Fig. 7). The rings are the last phase of these transformations, which, examined either with the naked eye or by means of a lens, are very curious, and may be said to form a real *electric kaleidoscope.**

The production of these figures is explained by the great mobility of the luminous arcs or filaments which compose the ovoid flame formed between the water and the electrode. A careful examination of this form of spark proves that there is in reality a kind of tassel or *brush*, analogous to the brushes of static electricity, but more complete by reason of the greater quantity of electricity coming into play. These luminous filaments being in a state of continual agitation, the points where they meet the surface of the liquid are constantly displaced, and form the rays observed. Their gyratory motion arises from the flow of the electric discharge. As to the rings, these are formed, in a manner visible to the eye of the observer, by the motion, more or less rapid, of the blue points, and by the persistence of the impression on the retina.

When the metallic electrode is positive, and the distilled water negative, the spark still assumes an ovoid form; but the middle is traversed by a core of violet light. When two metallic electrodes are employed, a luminous spheroid is obtained, the interior of which is traversed by a brilliant track. This appearance resembles that of the path and corona of the spark from currents of induction, except that here the corona occupies a proportionally greater space by reason of the greater quantity of electricity. In fact, if the length of the interposed column of water is considerably augmented, nothing but an arc or rectilinear track is obtained.

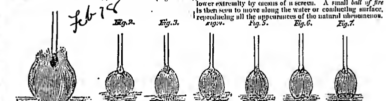
In these experiments it is not necessary to bring the electrode into actual contact with the water to determine the passage of the electric discharge. The tension of the battery, although the component couples are not very highly insulated, is sufficiently great to cause the spark to occur spontaneously through a distance of about 1 mm. from the surface of the liquid.

This current will also flow through rarefied air, and brilliantly illuminates Geissler tubes if not too much attenuated, producing the stratifications observed under analogous conditions by MM. Gassiot, Warren de la Rue, and H. W Müller. With a long column of water in circuit it is possible, with a single discharge from the battery, to keep a Geissler tube illuminated for upward of three hours and a half, owing to the small quantity of electricity expended in passing through the rarefied air.

These experiments form a sequel to those which I have already made known in explaining the mode of formation of the *globular thunderbolt*. They show that with electricity of sufficient quantity and tension one can obtain not only electrified liquid globules, but also the electric spark itself in the globular form. This kind of thunderbolt should, therefore, result from the production of an abundant flow of electricity in the dynamic state, in which quantity is joined with high potential. The particular case in which fulminatory globes present slow movements or become stationary is explained by the motion or repose of the column of moist air, highly electrified and invisible, which serves as an electrode. To imitate this effect it is only necessary in one of the preceding experiments to cause the electrode, previously suspended in the form of a long pendulum, to vibrate above a vessel filled with water, or a metallic surface, and to hide its lower extremity by means of a screen. A small *ball of fire* is then seen to move along the water or conducting surface, reproducing all the appearances of the natural phenomenon.

* These phenomena are comparable with those observed by M. Fernet with induction currents; they also offer a close resemblance to those which result from the falling of liquid drops upon a plane surface, and which have been examined by MM. Helmholtz, Thomson, Maxwell, Tait, Rogers, Worthington, Trowbridge, &c.

Feb 78



PLANTE'S ELECTRICAL EXPERIMENTS.

ELECTRICAL EXPERIMENT. 78—We find the following in the *English Mechanic*: "If an ebonite electrophorus be whipped with a fox-tail, it is negatively excited, and the condenser gives positive sparks. If, again, the electrophorus be rubbed with leather on which is some mosaic gold, the ebonite disk is positively excited, and the condenser gives negative sparks. It is stated by M. Schlosser, however, (*Pogg. Ann.*), that if the same ebonite disk be excited on one side with the fox-tail, and on the other with mosaic gold on leather, one may at any moment obtain from the same disk positive or negative electricity, according as the one or the other surface of the electrophorus is used as the source. The most important point in this double excitation is the very much greater length of spark, as is readily observed by the eye. On the other hand, considerably shorter sparks are obtained from the same electrophorus when both sides are similarly excited—for example, whipped with the fox-tail.

We add to the above that this experiment is quite old, and perfectly conforms to the known laws of electricity. Any non-conducting disk, whether glass, shellac, or ebonite, can be made far stronger electric when charged with opposite electricities on its opposite surfaces, than when charged with the same kind, as the mutual attraction of the opposite kind favors the charged in the first instance, and the mutual repulsion of the same kind interferes in the second case.

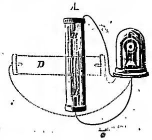
IS GRAVITY A MODE OF MOTION?

IN his 24th series of experimental researches Professor Faraday describes the experiments undertaken, the results of which, he says, though "negative, do not shake my strong feeling of the existence of a relation between gravity and electricity, though they give no proof that such a relation exists." In 1859, returning to the same investigations, he reflects upon the infinity of actions in nature, in the mutual relations of electricity and gravity, which would come in play: he pictures the planets and comets, charging themselves as they approach the sun; cascades, rain, rising vapor, circulating currents of the atmosphere, the fumes of a volcano, the smoke in a chimney, become so many electrical machines. Many more experiments were made by Faraday, but the results were still negative, and the experimenter did not accept them as conclusive. In this position the question remains to the present day; it may be, as Professor Jevons has suggested, that the effect was too slight to be detected, or it may be that the arrangements adopted were not suited to develop the particular relation which exists.

The force of gravity, while conforming on one hand to experience, is on the other a mysterious existence. We know that it is proportional to mass and utterly independent of present or intervening matter. In common with light, sound, and other influences emanating from a point, the law of decrease of its intensity is inversely as the square of the distance, yet, unlike the former, its action appears to be absolutely instantaneous.

The hypothetical ether which transmits light undulations which according to Herschel exercise a pressure of 17 billion pounds per square inch, and is harder and more elastic than adamant, is not influenced by gravitation as matter is, but its density and mechanical properties are modified by gravity in a way yet unexplained. Science thus far has stood silent before this mysterious influence, and there have not been wanting those who, like the late Professor Vince of Cambridge, have held that the force could be explained in no other way than by ascribing it to the immediate and ever present action of the Deity, an easy way of settling problems not wholly satisfactory to scientific minds.

The reader will now perceive the possible importance of an experiment which in place of Faraday's negative results has caused positive ones, and by which an electric current seems to have been produced by the direct action of gravity alone. Professor F. J. Pirani, Lecturer on Natural Philosophy and Logic in the University of Melbourne, writes to Professor Clerk Maxwell (who communicates the fact to *Nature*) with reference to the fact that a greater electric motive force is required to produce a given current between zinc electrodes in a solution of sulphate of zinc when carried upward instead of downward, testing the question whether a current should exist if two zinc electrodes connected by a wire are immersed in a solution of sulphate of zinc, the direction of the current being from the upper to the lower electrode. Professor Pirani used a glass tube, A, 18 inches long, filled with a saturated solution of sulphate of copper and closed with copper caps, B, with wires attached. This, on being attached to a Thomson static galvanometer, C, produced a deflection of 200 divisions when the tube was held vertically, the direction of deflection being reversed when the tube was reversed. When the tube after being held vertically was placed horizontally, as at D, the deflection diminished, and after several minutes the index came to zero.



Professor Maxwell has repeated the experiment, and considers that the temporary permanence of the deflection after the tube is placed horizontally indicates the possibility of something being shifted from end to end when the tube was inverted, but which remained where it was when the tube was only laid on its side.

Further verification of this experiment will be looked for with the greatest interest, as, if its present import be substantiated, the possible conversion of gravity into electricity places that force at once in the same category as light and heat, and indicates future possibilities in discovery over which now it would be idle to speculate. One, at least, may be the measurement of the velocity of propagation of the influence, and the means for determining this are probably already in existence, as will be seen by an examination of the horizontal pendulum, to the illustration and description of which we devote the first page of this issue.

(i.) That the electric currents are not produced by chemical action. (ii.) Nor by a temporary disassociation of the constituents of the liquid. (iii.) Nor by the action of gases occluded in the metals. (iv.) But that they are produced purely and solely by the heat, and that heat disappears in producing them. (v.) That they are immediate or direct effects of the heat, and that aqueous conducting liquids, therefore, possess true thermo-electric properties. (vi.) That the current is a result of a difference of thermic action at the surfaces of the two pieces of metal. (vii.) That it is a product of a suitable molecular structure of the liquid, a change of such structure resulting from alteration of temperature, and a direct conversion of heat into electricity; and (viii.) That the circumstance which is most influential in enabling heat to produce the currents, and most determines their direction and amount, is a suitable molecular structure of the *liquid*.

Irregular molecular changes in several liquids examined have been discovered, and it is suggested that the method should be further used to prosecute researches in this direction. In the case of platinum, when immersed in some saline, alkaline or acid liquids, a slight rise of temperature takes place, and a similar rise in temperature probably takes place when other metals are immersed. The results obtained support the contact theory of voltaic electricity.

GALVANIC CURRENT BETWEEN SOLUTIONS OF THE SAME SUBSTANCE OF DIFFERENT DEGREES OF CONCENTRATION.—J. Moser has observed that, in a couple formed by the same liquid of different degrees of concentration, a current passes from the more dilute to the more concentrated solution, the liquids being in separate vessels connected by means of a syphon, and having a metallic plate in each. This current was observed with zinc and sulphuric acid, with zinc sulphate, nitrate, chloride, and acetate, with copper sulphate and nitrate, iron chloride, silver acetate, and nitrate, &c. The electromotive force, however, is but feeble, the largest observed being only ·027 of that of a Daniell—as estimated by Du Bois-Reymond's modification of Poggendorff's compensation method—in a couple, consisting of a solution, containing 30 parts of $Cu\,SO_4, 5\,H_2O$ in 100 of water, and the same diluted with 29 times its volume of water. In this form of couple the metal is dissolved by the more dilute solution, and deposited from the more concentrated. June 78

SPECIFIC INDUCTIVE CAPACITIES OF CERTAIN DIELECTRICS.—It is important that authoritative determinations of specific inductive capacity should be made. Professors Ayrton and Perry, in a paper sent from Tokei, Japan, show that certain modifications must be introduced in the fundamental notions of the mathematical theory of electricity, because Faraday's conclusion as to the specific inductive capacity of all gases being the same as that of air is incorrect. Mr. J. E. H. Gordon has carried out some experiments in this direction by a new method, the essential features of which are that it is (i.) a zero method, (ii.) the electrified metal plates never touch the dielectrics, (iii.) no permanent strain is produced or charge communicated, as the electrification is reversed some 12,000 times a second. The following are the results obtained with solid dielectrics in plates 7 inches square and from ¼ inch to 1 inch thick:—

June 78

Dielectric.			Specific Inductive Capacity.
Ebonite, four slabs, ?, ½, ¼, ¼ in. thick	(1) 1·5593 (2) 1·5558 (3) 1·5671 (4) 1·5669	mean	1·56215
Best quality gutta percha			1·5939
Chatterton's compound			1·6080
Indiarubber (black)			1·5502
Ditto (vulcanised)			1·5988
Sulphur			1·6127
Shellac			1·6362
Solid paraffin S.G. ·9100 at 11° C. Melting point 68° C. Six slabs, each about ? in. thick	(1) 1·4986 (2) 1·4943 (3) 1·4920 (4) 1·5031 (5) 1·4936 (6) 1·5034	mean	1·49753
Bisulphide of carbon (probable)			1·4474
Chance's optical glass slabs nearly 1 in. thick	Double extra dense flint		1·6810
	Extra dense flint		1·6727
	Light flint		1·6677
	Hard crown		1·6872
Common plate glass, two slabs each, about 1in. thick	(1) 1·6933 (2) 1·6903	mean	1·6918

It will be seen that these figures differ considerably from those previously obtained, and we might suggest that other experimenters should spend a little time in confirming or in showing the incorrectness of these results.

ELONGATION OF A CONDUCTOR TRAVERSED BY A CURRENT.—M. Blondlot has presented to the French Academy of Sciences an account of some experiments undertaken with a view to prove whether or not there is really an elongation of a wire when a current passes in it, as Edlund and Streintz have believed and Wiedemann has denied. This method is designed to distinguish more clearly than heretofore between the effect due to heating and that due to the current. The principle of it consists in intercalating a thin metal ribbon in the circuit, by means of stout soldered connections. Any effect due to heating will dilate this ribbon both longitudinally and transversely, so as to increase its bulk without deforming it. But the current effect, if it take place, will do so unequally in the two directions, and will consequently deform the ribbon. Any misshaping of the metallic band or of figures traced on its surface ought therefore, M. Blondlot reasons, to be due to the current, and if there be none, such a direct mechanical action of the current does not exist. With the current from ten Bunsen cells no elongation could be detected, although the arrangement was capable of showing an elongation of 0·0000025m. per metre. Ribbons of brass, German silver, and other metals were experimented on, but with the same negative result. Nov 78

Scientif. Amer. Mar 20 1880

THE ELECTRO-MOTIVE FORCE OF ALUMINUM.

This subject has been recently studied by Signor Malavasi, of the Modena Academy. In contact with zinc (he says) aluminum always appears electro-positive, though it is less oxidizable. In dilute acid, on the other hand, it is electro-negative. If an aluminum plate be cleaned with oil and pumice stone, it is, on contact with zinc, positive; but, if it be cleaned with water and pumice stone and dried in the sun, it is negative. On being immersed in water after the cleaning with oil, the aluminum plate is only positive at the beginning—very soon negative. In water, the aluminum plate gets coated with a gelatinous mass (iron oxide, hydrate, and clay), the zinc plate with a crust; thus both are oxidized, with the above mentioned effects. Three elements—zinc, copper, water—have the same electro-motive force as five elements, zinc aluminum. On heating the junction, the current passes from aluminum to tin, copper, antimony; thus the behavior is somewhat like that of lead. At a higher temperature, the current between aluminum and tin is reversed. Aluminum plates are not markedly polarized in a circuit, though the positive aluminum electrode is thereby quickly dissolved. If the current is passed through after the aluminum plate has remained long in water, the polarization is more pronounced. In a combination zinc-aluminum water, or dilute acid, the current mostly rises at first, even to the double, and then slowly falls; and this the author attributes to the gradually strengthening adhesion of the water to the metals, especially the aluminum; the more so that, on carefully cleaning the aluminum plate with water and pumice, the rise takes place more quickly. This is also indicated by the increase of polarization, after long immersion, on the current being passed. This does not produce an increase of conductivity of the liquid. On alternately immersing, rinsing, drying, and again immersing, one of two aluminum plates, that remaining in the water, appears gradually positive, like zinc. In acid water, the change of the aluminum came out more strongly than in pure water. In copper aluminum elements, especially when the copper plate is large, the injurious polarization of the latter can be partly compensated by the rise in the electromotive force of the aluminum, so that thereby the decrease of current strength is partly prevented.

511

From a note presented to the French Academy it appears that Prof. Crova, of Montpel-

lier, has succeeded in measuring very high temperatures by observation of the changes undergone by spectral lines. He takes for term of comparison the heat developed in the wick of a moderator lamp fed with colza oil. This is reckoned equal to 1,000° in the optical scale (necessarily arbitrary) of temperatures. It is found that platinum, heated red in a gas lamp, gives 524. The white produced by an oxyhydrogen blow-pipe in the same metal corresponds to 810. The flame of a stearic candle is at 1,162, and that of an Argand burner, with ordinary coal gas, 1,373. The mixture of oxygen and coal gas projected on lime gives 1,806; the electric light developed by 60 Bunsen elements 3,060; and solar light 4,049. Prof. Crova is hopeful of the application of his method to measurement of stellar temperatures on the one hand, and on the other to the surveillance (in a more practical way) of numerous metallurgical and industrial operations. He promises an extended memoir on the subject.

May 78

ACTION OF MAGNETISM ON CIRCULARLY POLARISED LIGHT.

It is known to have been demonstrated by Fresnel, that a rectilinearly polarised beam of light passing through a quartz plate at right angles to the axis, may be decomposed into two rays circularly polarised in different directions, propagated in this crystal with unequal velocities. This phenomenon corresponds to a rotation of the plane of polarisation of the incident ray. M. Henry Becquerel has recently inquired whether the same holds for the magnetic rotation of the plane of polarisation discovered by Faraday; whether, accordingly, a circularly-polarised light ray, passing through a piece of heavy flint glass, subjected to the action of magnetism, may undergo an acceleration or retarded action while the magnetism acts.

The mode of experiment was as follows: Rays from a lime-light were circularly polarised by a Nicol and a doubly refracting crystal plate; then, made parallel by a lens, they passed through two slits situated very near each other, so that they were divided into two portions, each of which passed through a parallelopipedon of heavy flint-glass, and were then so united that they formed interference-fringes, which were observed with a lens. Of the two parallelopipeda, one was placed between the armatures of a strong horse-shoe electro-magnet, the other beyond the armatures in the prolongation of the line of poles. The magnetism then acts on the two glasses oppositely, and on the second more weakly than on the first. If the light rays experience a difference of passage by reason of the action of magnetism, the interference-fringes must be displaced.

When M. Becquerel accordingly sent a current through the electro-magnet, he observed a slight displacement of the fringes, and this displacement was now right, now left, according to the direction of the current. When he turned the doubly-refracting plate round through 90°, the direction of the circular motion was reversed, and it was observed that, for one and the same direction of the magnetisation, the direction of displacement of the fringes was reversed.

Certain errors through displacement of the entire system M. Becquerel excluded by direct experiment. He could now measure the amount of rotation of the plane of polarisation by magnetism, and found it, for the one parallelopipedon between the poles, 20° 15' of the micrometer, and for the other 4° 11' in the opposite direction; hence altogether a rotation of 24° 26'. From this, according to Fresnel, the displacement of the fringes will be = 0·067; and observation gave an actual displacement of about 0·07 fringes.

"The foregoing results," says M. Becquerel, "show that the phenomenon of magnetic rotation of the plane of polarisation is accompanied by a change of the velocity of propagation of the two light-rays circularly polarised in opposite directions; and it is not without interest to see how the direction of the circular light vibration is of influence in the same degree as the direction of the electric current which produces the magnetism; a phenomenon, which was theoretically foreseen, and of which the experiment described gives experimental confirmation.

51

ELECTRICAL INDICATOR FOR SHOWING THE ROTATION OF THE EARTH.

BY GEORGE M. HOPKINS.

Although the apparent displacement of the plane of vibration of the pendulum had long been noticed, it was not until the year 1852 that the fact was coupled with the diurnal rotation of the earth. In September of that year M. Foucault, a distinguished French physicist, suspended a ball, by means of a fine wire, from the dome of the Pantheon at Paris, and for the first time in the history of the world made visible the rotation of the earth. The pendulum thus formed, after receiving an impulse, vibrated for many hours, and preserved its plane of vibration while the earth slowly turned under it. This splendid experiment was subsequently repeated at the Capitol at Washington, and at other places, and is now about to be again performed in Paris.

Soon after the pendulum experiment, Foucault, to illustrate the same thing, constructed a gyroscope which was a modification of Bohnenberger's machine. This gyroscope received a rotating impulse from the hand of the operator, and the momentum of the disk was depended on to continue the rotation for a sufficient length of time to exhibit the movement of the earth.

The duration of the rotary movement thus produced must have been short, and the result unsatisfactory.

Recognizing the desirability of a more practicable means of making visible the diurnal movement of the earth, I have made the action of the gyroscope continuous by applying electricity as a propelling power.

In the first engraving (which represents the machine arranged for the purpose named) the rectangular frame which contains the wheel is supported by a fine and very hard steel point, which rests upon an agate step in the bottom of a small iron cup at the end of the arm that is supported by the standard.

The wheel spindle turns on carefully made steel points, and upon it are placed two cams—one at each end—which operate the current-breaking springs.

The horizontal sides of the frame are of brass, and the vertical sides are iron. To the vertical sides are attached the cores of the electro-magnets. There are two helices and two cores on each side of the wheel, and the wheel has attached to it two armatures—one on each side—which are arranged at right angles to each other. The two magnets are oppositely arranged in respect to polarity, to render the instrument astatic.

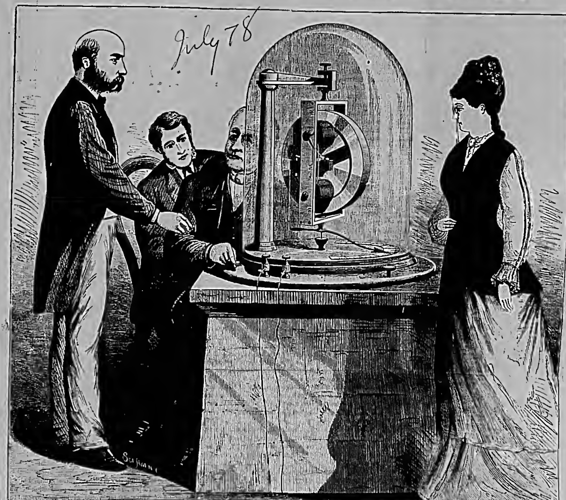
An insulated stud projects from the middle of the lower end of the frame to receive an index that extends nearly to the periphery of the circular base piece and moves over a graduated semi-circular scale. An iron point projects from the insulated stud into a mercury cup in the center of the base piece, and is in electrical communication with the platinum pointed screws of the current breakers. The current-breaking springs are connected with the terminals of the magnet wires, and the magnets are in electrical communication with the wheel supporting frame.

One of the binding posts is connected by a wire with the mercury in the cup, and the other is connected with the standard. A drop of mercury is placed in the cup that contains the agate step to form an electrical connection between the iron cup and the pointed screw. The instrument is covered with a glass shade to exclude air currents, and the base piece is provided with leveling screws.

The current breaker is contrived to make and break the current at the proper instant, so that the full effect of the magnets is realized, and when the binding posts are connected with four or six Bunsen cells the wheel rotates at a high velocity.

The wheel will maintain its plane of rotation, and when it is brought into the plane of the meridian the index will appear to move slowly over the scale in a direction contrary to the earth's rotation, but in reality the earth and the scale with it move from west to east, while the index remains stationary, or nearly so.

[Continued on page 4.]



ELECTRICAL INDICATOR FOR SHOWING THE ROTATION OF THE EARTH.

ELECTRICAL INDICATOR FOR SHOWING THE ROTATION OF THE EARTH.

[*Continued from first page.*]

If the index were absolutely motionless the scale would move under it at the rate of 15° an hour, but owing to friction the motion of the scale or apparent motion of the index is less.

It makes no difference whether the index points northward or southward, its apparent motion is always westward, thus affording visible evidence that the earth rotates.

The instrument I have thus described may be easily modified, so as to illustrate other interesting phenomena of rotary motion.

By removing the index and point from the insulated stud at the lower part of the frame and unscrewing the supporting piece from the top of the frame, the frame may be suspended in a horizontal position upon jointed screws in a fork which is supported upon a vertical pivot, as shown in the second engraving.

Fig 2

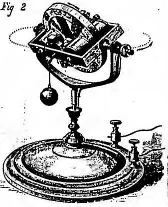


Fig. 2.—ELECTRICAL INDICATOR.

The pointed screw that enters the insulated stud is insulated, and communicates, by an insulated wire, with mercury contained in an annular vulcanite cup on the fork supporting pivot. One of the binding posts is connected with the pivot of the fork and the other communicates with the mercury in the vulcanite cup.

When the instrument is connected with a battery the wheel revolves rapidly, and if undisturbed will remain in the position in which it was started. If a small weight, such as a key, be hung upon one of the pivot screws of the wheel spindle, the frame containing the wheel does not turn quickly on its pivots as might be expected, or as it would if the wheel were not revolving, but the entire apparatus immediately begins to revolve slowly on the vertical pivot, while the weighted side of the frame descends almost imperceptibly. Transfer the weight to the opposite pivot, and while the wheel still revolves in the same direction the apparatus will revolve on the vertical pivot in the opposite direction. The rotary movement on the vertical pivot is in opposition to the friction of the wheel; that is, the apparatus if rotated on the vertical pivot by the friction of the wheel on its pivots would be in the opposite direction.

By removing the weight from the pivot screw and turning the apparatus on the vertical pivot the converse of what has just been described will result; that is, the wheel besides revolving on its own axis will turn in a plane parallel with its axis.

If the apparatus be turned on the vertical pivot in the opposite direction the rotation of the wheel on its new axis will be reversed, and by oscillating the apparatus on the vertical pivot the wheel and frame will revolve rapidly on the pointed screws that support the frame.

The law controlling these movements is as follows: "Where a body is acted upon by two systems of forces, tending to produce rotations about two separate axes lying in the same plane, the resultant motion will be rotation about a new axis situated in the same plane between the directions of the other two."

By means of this continuously operating gyroscope Dr. Magnus' experiments showing some of the causes of deviation of projectiles may be nicely exhibited.

OXIDATION OF GOLD BY GALVANIC ACTION.—Grotthus, says Mr. Berthelot, observed that a gold wire is dissolved when employed as the positive terminal of a circuit in sulphuric acid. The author confirms these results, and shows that under similar circumstances nitric acid also dissolves gold. This is due neither to ozone nor, as suggested by Chevreul, to persulphuric acid, for neither of them has any action on gold.

When two charges are shared in this way there is a loss of energy. For the total energy at first is

$$\tfrac12 S_1 V_1^2 + \tfrac12 S_2 V_2^2,$$

but after sharing, it is $\tfrac12 (S_1 + S_2)V^2 = \tfrac12 \frac{(S_1 V_1 + S_2 V_2)^2}{S_1 + S_2}$.

So, if w is the loss of energy,

$$2w(S_1 + S_2) = (S_1 V_1^2 + S_2 V_2^2)(S_1 + S_2) - (S_1^2 V_1^2 + 2 S_1 S_2 V_1 V_2 + S_2^2 V_2^2) = S_1 S_2 (V_1^2 + V_2^2 - 2 V_1 V_2).$$

Hence

$$w = \tfrac12 \frac{S_1 S_2}{S_1 + S_2}(V_1 - V_2)^2.$$

A necessarily positive quantity. This is the energy of the sharing spark.

ANSWERS TO QUERIES.

7. "J. Davies" asks in what does potential, as applied to electricity, differ from potential as applied to energy? He should consult some handbook of telegraphy—say Preece and Sivewright's; but, meanwhile, he may be helped by the following rough explanation. The term has the same signification applied to both, namely, the efficient power capable of being but not yet exerted. As applied to energy, it takes into account mainly the resistance to be overcome. Electrical potential often involves more complex conditions. The measure of electro-motive force is represented by the difference of electrical potentials at two points, and, when earth is used, both are referred to the electrical potential of the earth. Strictly speaking, the potential value of a current will be determined by the difference between the differences of potentials at the two points. J. L.

8. If "J. W." is under eighteen years of age, and is in other respects eligible, he can obtain a nomination for the Postal Telegraph service by applying to the Secretary, General Post Office, London. J. L.

QUERIES.

17. Will you explain to a puzzled party how the two opposite poles of an electro-magnet attracts the plate on the hammer of an electric bell, which is *charged* with one of the same kind of electricities of one of the poles of the said electro-magnet? We imagine that the two opposite poles should neutralise each other in respect to a body *charged* with an electricity of the kind of one of the poles. A SUBSCRIBER.

THE PHYSICAL SOCIETY—JUNE 8TH.

[CONTINUED.]

THE ELECTRICAL PROPERTIES OF BEES' WAX AND LEAD CHLORIDE.

Professor REINOLD at the last meeting of the Physical Society read a paper by Professor W. E. Ayrton, of the Imperial College of Engineering, Tokio, Japan, on "The Electrical Properties of Bees' Wax and Lead Chloride." The author stated that, in the two papers by Professor Perry and himself on Ice as an Electrolyte Result, read before the Physical Society, they showed that both the conductivity and specific inductive capacity of $\left\{\begin{matrix}\text{ice}\\\text{water}\end{matrix}\right\}$ increased regularly without discontinuity in passing from several degrees below the freezing point to several degrees above it. They drew attention to the fact that, in consequence of the absorbed charge in water being immeasurably greater than the surface charge, they could not hope by any method of experimenting to properly compare the true specific inductive capacity with the index of refraction for light of infinitely long waves, so that, in fact, the only support that Professor C. Maxwell's electro-magnetic theory of light could hope to derive from these experiments must be based simply on the fact that in $\left\{\begin{matrix}\text{ice}\\\text{water}\end{matrix}\right\}$ both the specific inductive capacity and the index of refraction increase as the temperature rises. At the meeting of the Society in November, at which the second of their two papers was read, Professor G. Foster mentioned that he was gathering together all the results obtainable, connecting specific inductive capacity with index of refraction. He (Professor Ayrton) therefore begged to forward, as a contribution to this collection, the following results of some further experiments which he had been making on this subject. For the last two years his attention had been turned to wax as a good material for electrically testing, especially in regard to the connection which, in their paper on the "Viscosity of Dielectrics," communicated to the Royal Society, they pointed out existed between high specific inductive capacity and low specific resistance. He therefore had constructed a large condenser, consisting of many sheets of letter paper soaked in melted bees' wax, with alternate sheets of tin-foil. After the condenser was built up in the usual way, melted bees' wax was poured in, the plates squeezed together, and the whole shut up in a fairly good water-tight wooden box. The condenser was buried several feet under ground to insure uniformity of temperature, connexion being made with the insulated coating by a piece of Atlantic cable core and with the other coating by a piece of bare copper wire. After this condenser had been buried for a short time it showed the apparently abnormal condition of diminution of resistance by electrification. This phenomenon then formed the subject for special investigation with this condenser. As beeswax is one of the few substances in which the index of refraction for light increases in passing from the liquid to the solid state, it seemed important in connection with the electro-magnetic theory of light to carefully measure the specific conductive capacity of a wax condenser as it was gradually cooled through the solidifying point. A small shallow clean copper box, 19 centimetres long by 17 centimetres wide, was therefore lined with a sheet of letter-paper 0·036 centimetres thick, previously well soaked in melted beeswax. A clean copper disc 12·8 centimetres in diameter was placed on the top, weighted down, and the dish filled up with melted wax. This condenser, A B was heated in an oil bath, *C D*; E and F are holes for the insertion of thermometers, of which the bulbs were just above the wax condenser; *G* is an opening through which the insulated electrode, H, of the condenser may protrude without touching the oil bath. A wooden stand, W W, supported the condenser in the middle of the bath, and a glass vessel, V, holds strong sulphuric acid to keep the inside space artificially dry. The bath is closed by a double door, which is made to fit well by a strip of leather inserted between it and the bath. The condenser having been inserted, the bath was heated to about 90° C, and kept at that temperature for some time; the lamps were then removed, when the temperature fell very slowly. The capacity was then measured (several observations being made at each temperature) by charging the condenser with 75 Daniells cells joined in series and discharging it through an exceedingly delicate Thomson's reflecting galvanometer. The curves obtained (on three different days) did not give the same capacity for the same temperature, but, considering, first, the very small capacities that had to be measured, and, secondly, the difficulty of accurately determining the temperature of a non heat-conductor like wax, even when enclosed in the oil bath, the discrepancies in the curves were not to be wondered at. One fact, however, was very striking in all three curves, and that was the *rise* in capacity as the temperature very slowly fell from about 80°, to 60°, and the subsequent diminution in the capacity on a still further diminution of the temperature. Probably, had experiments on capacity been made when cooling from a much higher temperature, there would have been observed, first, a gradual diminution in capacity due to cooling, down to about 80° C.; then they had the rise of capacity in the wax solidified at about 60° C.; and, lastly, they saw the subsequent rapid decrease on further cooling. Now, this was precisely in agreement with the changes known to occur in the index of refraction for light, and hence the interest of these experiments. As there was always a small electromotive force in the wax condenser, and, as the vibrations of the galvanometer needle were, as usual, damped by the air vane, he used for calculating the capacity the formula developed by Professor Perry and himself for employment in such cases ("A test for Determining the Position of a Partial Discontinuity without Earth-fault," by Professors W. E. Ayrton and John Perry, page 12). It might, of course, be at once objected that the rise in capacity, as the work cooled from about 80° C., to 60° C. was perhaps due not to any change in the specific inductive capacity, but merely indicated that the distance between the copper plates of the condenser was slightly diminished by the wax shrinking on solidifying. This solution, however, was impossible, since, although a sudden expansion of the wax on solidifying, if such an expansion existed, might have separated the plates, it was unlikely that the contraction, which really occurred could have brought them nearer together than the thickness of the paper by which they were separated when the wax was liquid. Nevertheless, partly to obtain additional evidence on this point, and partly to measure specific resistance, or resistance per cubic centimetre, of beeswax at different temperatures, he made ten distinct sets of experiments, occupying many days, on the conductivity of wax. In these experiments the wax condenser was heated up to about 130° C., and a current sent through it with the seventy-five Daniells cells in series. The temperature was kept constant at about 130° C., until the galvanometer deflection had reached its maximum, when it was considered that the wax had acquired the temperature indicated by the thermometer. The temperature was then allowed to fall very slowly, and frequent readings of the galvanometer and thermometer were taken. The results were shown by a diagram. In no curve was there *the slightest appearance* of a rise of conductivity at the melting point, which would probably have been obtained had the copper-plates approached one another in appreciable distance on the wax solidifying. They might, therefore, conclude that in the previous experiments the rise in the capacity at melting indicated a true increase in the specific inductive capacity coincident with an increase in the index of refraction for light. As regards apparent increase of resistance by electrification, which, as mentioned, he observed during repeated experiments, extending over some months, with the wax condenser buried under ground, the general conclusions arrived at were that, not only did the conductivity usually increase by electrification, but that it steadily increased day by day—a result indicating that the wax was deteriorating, probably from damp penetrating through the joints of the wooden box, in spite of leather having been inserted between the different parts of the wood before they were screwed together. This conclusion appeared to be correct, since on digging up the condenser and keeping it near a fire for many days, it regained its original high resistance. The damp must, therefore, not only have entered through the joints in the wood, but through some small cracks that were observed in the mass of wax when the condenser was opened, and it was probably due to this damp that the peculiar effects of polarization were observed similar to those noticed by the Comte du Moncel when testing stones, and by Mr. T. Warren in certain insulating oils. He now made a number of experiments with lead chloride as a dielectric—a substance to which his attention was particularly drawn by some remarks of M. Buff Ann. Chem. Pharm. cx., s. 258, 1859, in which he said that this substance conducts electricity like a metal that is without decomposition, a conclusion, however, which at first sight would appear to be negatived by certain experiments of Herr Wiedemann, published in Pogg. Ann. c. liv., 318—320, from which he found that the resistance of lead chloride diminished by increase of temperature. He (Professor Ayrton) first had made a small carbon box containing a carbon plate, but prevented from touching it by three small pieces of clean glass. The carbon plate had a carbon electrode attached to it, the whole being cut out of a solid piece of carbon, so as to have the shape of an inverted "T." Into the box lead chloride was poured in a fused state until it covered up the plate, but leaving the carbon electrode of the plate protruding for connection with the battery. The whole was then allowed to cool very slowly. The outer part of the carbon box and the end of the carbon electrode were now electrotyped, and copper wires soldered on, the junction of the carbon and copper being quite clear of the lead chloride. [The results observed with this condenser were given in a table showing twelve experiments on different dates.] In addition to the resistance of the condenser being measured while the battery was con-

nected, time readings were also taken with the galvanometer and the discharge from the condenser after the removal of the battery, as well as time-readings with an electrometer of the electromotive force in the condenser producing the discharge. As, however, diminution in the discharge and deflection was in each case quite regular, and curves were not given, it was interesting to observe, in the preceding table, that in every case there was a diminution of resistance by electrification, although in some cases there was an increase during the first minute. Looking at the first group of tests taken between November 13 and 15, they saw a gradual increase in the resistance day by day. Looking, also, at the second group of tests made between November 21 and December 4, they likewise saw a steady daily increase in the resistance, but, in the interval between November 15 and 21, when no tests were made, there appeared to be a decided diminution in resistance. Considering, however, that the tests taken on Nov. 13, and at the beginning, and on December 4, at the end of the investigation, gave almost identical results, it could not be concluded with certainty that there was any decided deterioration taking place in the lead chloride. But, on breaking up the condenser, the lead chloride was found to contain many small holes, so that it was possible that damp might have collected in these. This solution, however, would, at first sight, appear to be rather improbable, since the condenser, both when being tested, and when not tested, was kept in an atmosphere kept partially dry with sulphuric acid. Some fresh lead chloride was prepared in the same way as before—that is, by precipitating from a solution of lead acetate with a solution of common salt, and carefully washing the precipitate several times with distilled water. But, the new condenser, made with the carbon box and plate, was found to have a resistance of only two megohms at 16° C., and, unlike what was experienced in the former case, the resistance in all the experiments was now found to increase by electrification. This, however, was probably explained by the fact that whereas in the previous case 33 volts electromotive force was used, now only one volt was employed, so that decomposition—whether of the lead chloride itself, or of the damp, which, after decomposition, might act on the chloride—was probably not produced. Some preliminary temperature tests were now made, and, in accordance with Herr Wiedemann's results, he found that the resistance diminished with elevation of temperature. The condenser was now left in an atmosphere dried with sulphuric acid from December 21 to January 7, when it was found that the resistance had increased to about 15·6 megohms at 70° C. A large number of measurements of the conductivity at different temperatures, using the same oil bath for raising the temperature, were now made. The different experiments gave results nearly agreeing. The representative curve was approximately logarithmic, that is, the ratio of the difference of the logarithms of the conductivities to the difference of temperatures was approximately constant. Thinking that possibly the method previously employed for making the lead chloride by precipitating it from a solution of lead acetate with a solution of common salt might have introduced traces of some salt of lead other than the chloride, the following method was now employed for making another supply of the chloride. From a clear solution of lead nitrate a precipitate was formed with colourless hydrochloric acid, and the precipitate well washed with distilled water. A third condenser was now constructed, three small pieces of glass 0·225 centimetres thick being used to separate the carbon plate from the box. The connections with the box and plate were made as before by first electrotyping the carbon with copper, and then soldering on copper wires, the junctions of the carbon and copper not being in contact with the lead chloride. A condenser was also made with a copper box and a copper plate, the two being well coated with graphite to protect them from the action of lead chloride, and separated from one another by three small pieces of glass 0·135 centimetres in thickness. Tests of conductivity were now made at different temperatures with both condensers, 0·075 volts being employed with the carbon, and 7·5 volts with the copper condenser, or sometimes 2·2 volts with the latter. With the carbon condenser and with the smaller electro-motive force the resistance was found to increase with electrification, whereas, with the copper condenser and with the electro-motive force 2·2 volts, the resistance diminished with electrification, and with 7·5 volts this diminution became much more rapid, these results being observed at both high and low temperatures. In the earlier experiments with this copper condenser the diminution was regular, whereas later on it proceeded irregularly; but, on the whole, it might be said that, when an electro-motive force not exceeding one and three-quarters volts was employed, there was an increase in resistance with electrification such as is usually experienced with gutta percha and with ordinary dielectrics, while when the electro-motive force exceeded this limit there was either a regular or an irregular diminution of resistance by electrification, the results apparently not depending much on whether carbon or copper coated with graphite was used for the plates of the condenser. As this limiting electro-motive force appeared to be about the same as that necessary to decompose water, he thought they might fairly conclude that the diminution in resistance was due to a decomposition of the damp (which appeared to be contained in the lead chloride even when careful means were taken to dry it), and to the products of the decomposition acting on the chloride.

EFFECTS OF ELECTRIC CURRENTS ON THE SURFACES OF MUTUAL CONTACT OF AQUEOUS SOLUTIONS.*

BY G. GORE, LL.D., F.R.S.

In the year 1858 I made the following experiments, for the purpose of ascertaining whether visible movements, similar to those obtained by passing an electric current through mercury and an aqueous solution, could be obtained by passing a current through the surface of mutual contact of two aqueous liquids alone:—

"1st. A definite layer of oil of vitriol was placed beneath a layer of distilled water weakly acidulated with sulphuric acid, and the terminal wires of a voltaic battery immersed in the upper liquid; no visible movements occurred at the boundary line of the two liquids.

"A dense solution of cyanide of potassium was placed in a small glass beaker, a few particles of charcoal sifted upon its surface, and a layer of aqueous ammonia, half an inch deep, carefully poured upon it. A vertical diaphragm of thin sheet gutta percha was then fixed so as completely to divide the upper liquid into two equal parts; the vessel was placed in a strong light, and two horizontal platinum wire electrodes, from sixty-six freshly charged Smee's cells, were immersed one-eighth of an inch deep in the liquid ammonia on each side of the diaphragm. A copious current of electricity circulated, but no movement of the liquids at their mutual boundary line could be detected." (See *Proc. Roy. Soc.*, vol. x, 1860, p. 235, par. 9).

Recently, also, I have made similar experiments, but in a much more searching manner, in order to ascertain whether an electric current, passing between two aqueous liquids, affects their diffusion into each other. The essential difference in the form of these experiments from that of the above-mentioned ones was to concentrate the action of the current upon a very much smaller surface of contact of the liquids, and thus render any visible effect upon their diffusion more manifest.

After making several forms of apparatus, in order to obviate certain difficulties of manipulation which arose and were fatal to success, I found that, when an electric current was passed between the surfaces of mutual contact of certain aqueous solutions of different specific gravities, the boundary line of contact of the two liquids became indefinite at the surface where the current passed from the lighter into the heavier solution, and became sharply defined where the current left the heavier liquid and re-entered the lighter one; and that on reversing the direction of the current several times in succession after suitable intervals of time, these effects were reversed with each such change. Also, in various cases in which the contiguous boundary layers of the two liquids had become mixed, the line of separation of the two solutions became, by the influence of the electric current, as perfect as that between strata of oil and water lying upon each other. In rarer cases two such distinct lines of stratification appeared. Other new phenomena were also observed.

As I have sought, without success, for any record of previous discovery of essentially similar effects, and as it is evident that those I have observed belong to a large class of similar phenomena, I beg leave to take the earliest opportunity of submitting this brief statement to the Royal Society.

* Abstract of a Paper presented to the Royal Society.

Electrician May 1 1880

ANALOGY BETWEEN FLUIDITY AND GALVANIC CONDUCTIVITY.

Scientific American Supplement Apr 17 1880

O. Grotrian finds an interesting relation between the reciprocal of the constant of friction in fluids and the galvanic conductivity of a number of salt and acid solutions. Let t designate the temperature of the fluid, f the temperature coefficient of fluidity, and k the conductivity. Then the value of the coefficient, $\frac{df}{dt}\frac{1}{f}$, in a change of concentration, always alters in the same direction as the corresponding coefficient of conductivity, $\frac{dk}{dt}\frac{1}{k}$.—*Wied. Ann.*

THE ELECTRICAL INDICATOR FOR SHOWING THE ROTATION OF THE EARTH.—A NOTE FROM PROF. MAYER.

To the Editor of the Scientific American:

The reading of the article by Mr. George M. Hopkins on the "Electrical Indicator for Showing the Rotation of the Earth" has suggested an addition to the apparatus which will render the experiments with it more delicate, and make manifest the rotation of the earth after the gyroscope has run for only a minute. If he will attach a plain or concave mirror to the frame of the gyroscope and reflect a beam of light from the mirror to a screen he will have an index which may be of considerable length, of no weight, and have no momentum. If the distance of the screen from the mirror is, say, ten feet, then the spaces over which the light passes on the screen will be the same as those which would be passed over by a rod 20 feet long attached to the gyroscope as an index. This is because the angle of deflection of the reflected beam is always double of that of the angular deflection of the mirror.

The apparent angular motion per hour of Foucault's pendulum and of his gyroscope for showing the earth's rotation is equal to 15° multiplied by the sine of the latitude of the place where the pendulum or gyroscope is mounted. Calling the latitude of New York 40° 42′, we have 9°·47′ as the amount of hourly motion in azimuth. But as the reflected beam moves through double the angle of the mirror attached to the gyroscope, we have 19° 34′ as the hourly angular motion of the reflected beam of light. In one minute of time the beam will move through $\frac{1}{60}$ of 19° 34′, or through 19½ minutes of arc. This angular displacement of the beam will equal ·678 of an inch on a screen ten feet distant from the mirror. In ten minutes of time we will consequently see the spot of light on the screen move through $6\frac{78}{100}$ inches. This quantity, however, gives the motion during the first ten minutes, if we suppose the beam to have started for a direction at right angles to the screen. The distance through which the spot of light travels will be greater during succeeding 10 minutes of time, for the distances will be the tangents of the angular deflections. If, however, the screen have a cylindrical surface with a radius equal to the distance of the axis of rotation of the gyroscope to the screen, then the spot of light will travel over equal distances in equal successive portions of time.

For accurate measurements of the motion of the gyroscope it will be better to place a horizontal scale of equal parts facing the mirror at the distance of, say, five to ten feet, and view the reflection of this scale from the mirror by sighting through a telescope with cross threads in its focus. With such an arrangement (see Article XI. of the "Minute Measurements of Modern Science," in the SCIENTIFIC AMERICAN SUPPLEMENT, by the writer) two or three minutes' observation on the motion of the scale over the cross threads of the telescope will suffice to give the amount of angular motion, which may be compared with that which theory requires, and which is computed by any one who has a table of natural sines. He will find the sine corresponding to the angle of the latitude of the place, and multiply this by 15° (the hourly angular motion at the poles of the earth); he will then take $\frac{1}{60}$ of the product for the angular motion in one minute, and double this result to allow for the doubling of the angle of reflection.

Foucault suspended his gyroscope by a strand of untwisted silk fibers, and if Mr. Hopkins will adopt this mode of suspension in place of the steel point, he will get rid of the friction, which should be avoided. There is a good description of Foucault's gyroscope, with four engravings, in Arago's "Astronomie Populaire," volume 3, page 50, *et seq.*

I have during the past winter repeated the Foucault experiment with the pendulum, and the apparent hourly angular motion of the instrument corresponded quite well with the theoretic value. The bob of my pendulum was a thirty pound cannon ball, which I floated in a hemispherical bowl containing mercury, and thus found out the position the ball has when its center of gravity is in a vertical line with its center of figure. The ball was suspended in the same position it had when it floated in the mercury.

ALFRED M. MAYER.

South Orange, N. J., July 1, 1878.

Electrical Indicator for Showing the Rotation of the Earth.

To the Editor of the Scientific American:

In my article on an "Electrical Indicator for Showing the Rotation of the Earth," in your issue of July 6, I mention that the apparent motion of the index is 15° per hour. With this instrument this would be true only at the poles, at the equator it would be 0°, and in this latitude it would be about 9°.

I intend soon to furnish you with sketches of another form of instrument, which will indicate the full diurnal motion when placed at any point on the earth's surface.

GEO. M. HOPKINS.

ON THE MAGNETIC ROTATION OF THE PLANE OF POLARIZATION OF LIGHT UNDER THE INFLUENCE OF THE EARTH. BY HENRI BECQUEREL.—In the course of my investigations on magnetic rotatory polarization I have been led to the direct estimation of the action of terrestrial magnetism upon various substances. This action can be very neatly made evident by an experiment which seemed to me sufficiently interesting to be communicated to the Academy. Between a Jellet polarizer and an analyzer furnished with a telescope and mounted on a divided circle is placed a tube of half a metre length, terminated by parallel glass plates and containing bisulphide of carbon. At the two ends of the tube plane mirrors, arranged as Faraday arranged them, gave several successive reflections of the luminous ray, and thus augmented the observed rotation. In the present experiment the second reflection could be viewed; the ray had therefore traversed the tube five times, corresponding to a thickness of 2·5 metres of bisulphide of carbon. The source of light was a pipe with oxyhydrogen gas. A great amount of light was lost by absorption and by the successive reflections, and the rays transmitted to the eye were chiefly the yellow rays. The entire system was firmly fixed to a horizontal copper rule, and could turn about a vertical axis so as to orient the luminous beam in various directions. With this arrangement it is ascertained that, if the system be made to coincide in direction with the plane of the magnetic meridian, the same position of the polarization-plane is not obtained whether we look towards the south or towards the north; a great number of closely concordant measures gave an angular difference of about 6′·5 between the two positions. On the contrary, if we place ourselves in a position perpendicular to the magnetic meridian, we get the same direction of the plane of polarization whether we look towards the east or towards the west, and this position is the bisectrix of that which we have in viewing towards magnetic north and south. It may hence be concluded that the angular difference observed is a rotation of the plane of polarization of the light, due to the action of the earth; the number 6′·5 measures the double of the rotation for yellow light and in the special conditions of the experiment. The direction of this rotation is the same as that of the rotation of the earth; it is the direction of an electric current which, on the hypothesis of Ampère, would give rise to the phenomena of terrestrial magnetism. It must be remarked that the number we have given only refers to observations made in the laboratory of the Muséum d'Histoire Naturelle, in proximity to more or less considerable masses of iron. To ascertain with more precision the action of the globe, and to utilize this method for estimating the intensity of the earth's magnetism, it would be necessary to use the same precautions as for ordinary observations of terrestrial magnetism, and to amplify the phenomenon by taking a longer tube. This is what I am at present engaged in. The system arranged as above indicated exhibits remarkable sensitiveness to the action of magnetism; an ordinary bar magnet held in the hand, and brought parallel near to the tube, first in one direction then in the other, is sufficient to make manifest a rotation of the plane of polarization that may attain to upwards of 1°. It is interesting to compare this direct measurement with an estimation made by Mr. Gordon* of the magnetic rotation produced by 1 centm. of bisulphide of carbon under a magnetic action equal to unity. The result found by calculating from this number the action of the terrestrial horizontal component is that 2·5 metres of bisulphide of carbon should give, with yellow light, a single rotation of 3′·8 instead of 3′·25, which results from our direct observation. The difference may be due to exterior perturbations. If we adopt the latter number we see that, under the conditions in which we have placed ourselves, the double rotation of 1 metre of bisulphide of carbon would be 2′·6, and that of 1 metre of water 0′·8.—*Comptes Rendus de l'Académie des Sciences*, April 29, 1878.

ON GALVANIC CURRENTS BETWEEN SOLUTIONS OF DIFFERENT DEGREES OF CONCENTRATION OF THE SAME SUBSTANCE, AND THEIR SERIES OF TENSIONS. BY DR. JAMES MOSER.—The electromotive force of liquid galvanic series is influenced by the concentration of the liquids. In order to determine the nature of this influence, I have investigated, in the laboratory of Professor Helmholtz, liquids with which it is possible to isolate this influence of the concentration. All chemical processes were to be excluded; therefore, only differences of concentration might exist, or changes in it occur during the passage of the current. Likewise, for the elimination of all chemical actions, it was necessary that the electrodes should consist of that metal which was contained in the solution. Two glasses with differently concentrated solutions of the same salt were connected by a siphon; and the circuit was closed by a metallic conduction with the electrodes just mentioned. I then observed, in all the cases investigated, *that a current arises which proceeds from the more dilute to the more concentrated solution.* It may be represented thus:—

Zn, dilute $ZnSO_4$, concentrated $ZnSO_4$, Zn.

This current appeared regularly in a series of solutions of

sulphate, nitrate, chloride, and acetate of zinc, sulphate and nitrate of copper, chloride of iron, acetate, and nitrate of silver, &c. I observed the electromotive forces of these series by Poggendorff's method of compensation, modified by Du Bois-Reymond, from a few thousandths up to one-fifth of a Daniell, the latter force between very dilute and highly concentrated solutions of zinc chloride. I give, in the following table, the ten electromotive forces, between the combinations of two, of five solutions of sulphate of zinc, the unit being nearly 0·001 of a Daniell:—

100 parts of solution contain of $ZnSO_4+7H_2O$	15 per cent.	30 per cent.	45 per cent.	60 per cent.
1 per cent.	18	22	28	30
15 "	...	5	13	21
30 "	...	...	7	17
45 "	...	...	...	9

These numbers indicate a series of tensions; for, *e.g.*, the electromotive force between 15- and 30-per-cent. solution is 5, 30- and 60-per-cent. solution 17, 15- and 60-per-cent. solution 21. I then confirmed the existence of a series of tensions, by connecting with each other, by four siphons, five glasses, of which the 1st, 3rd, and 5th contained solutions of equal strength (45 per cent.), the second contained stronger solution (60 per cent.), the 4th weaker (15 per cent.). I immersed the one electrode in glass 1, the other successively in 2, 3, 4, 5. When the second electrode dipped in 3 and 5 I obtained no current, because the concentrations of the terminal solutions were equal; but, on the immersion of this electrode in glass 2, and in 4, there was always a deflection produced—in the one case by the electromotive force 9, between solutions of 45 and 60 per cent., in the other by the force 13, in the opposite direction, between 45- and 15-per-cent. solutions. I made the same experiments on a series of other salts, and thus determined the 15 electromotive forces between the couples formed by six solutions of cupric sulphate:—

	B	C	D	E	F
A	10	16	21	25	27
B	...	6	11	15	17
C	...	...	5	9	11
D	...	...	...	4	6
E	...	...	...	...	2

F was a solution containing, in 100 parts, 30 of crystallized salt ($CuSO_4+5H_2O$). One hundred parts by volume of this solution were mixed in E with 33⅓, in D with 100, in C with 300, in B with 700, in A with 2,900 parts of water. By these currents, going from the diluted to the concentrated solution, metal is dissolved in the diluted, and separated from the concentrated solution. Only when the concentration is the same in both solutions does the current cease. For the work accomplished by the current we should have to seek the corresponding equivalent in the work of the force of attraction between the salt and the water, which makes itself perceptible in the thermal actions which can be observed on mixing different solutions of the same salt. Accordingly, the current observed by me must be conceived as a reaction-current against the migration of the ions, as the polarisation-current is one of reaction against the decomposition-current; for, whenever any salt is electrolysed, the solution becomes more concentrated at the anode, more dilute at the cathode. My experiments show that then arises an electromotive force which acts in opposition to that of the electrolysing battery.—*Monatsbericht der kön. preuss. Akad. d. Wissensch. z. Berlin.*

Motion of Electricity in Insulated Telegraph Wires. By G. Kirchhoff.—Assuming that the induction effects produced by alterations of the current intensity may be neglected against the influence of the charges of an underground telegraph wire, Sir W. Thomson has referred the propogation of the electricity therein to the same laws as the conduction of heat. G. Kirchhoff develops this relation in connection with the equations developed by Helmholtz respecting the components of the current density ($u = -\lambda \frac{\partial \phi}{\partial x}$, &c., where λ denotes the conductivity) and of the electrostatic moment dependent on the dielectric polarisability ($a = -k \frac{\partial \phi}{\partial x}$, &c.), if ϕ denotes the electrostatic potential, which is a function of x, y, z and consists of three parts, arising—first, from the free electricity in and upon the conductor; secondly, from dielectric polarization; and, finally, from the double electric layer at the boundary surfaces of heterogeneous conductors. From the calculations, which cannot be given in abstract, it follows that $\Phi = e^{\beta z}\left(C \cos. (n t + a z) + C' \sin. (n t + a z)\right) + e^{-\beta z}\left(D \cos. (n t - a z) + D' \sin. (n t - a z)\right)$, which equation represents two passages of waves in opposite directions along the z axis of the wire, in which the height of each wave as it moves forward diminishes correspondently to the value β. The period for ϕ, according to the time, is $\frac{2\pi}{n}$; β and a are given by the equations

$$\beta^2 - a^2 = \frac{2\lambda}{\lambda_1 \rho_1^2 \log \frac{\rho_2}{\rho_1}}, \quad \beta a = \frac{n\mu}{\lambda_1 \rho_1^2 \log \frac{\rho_2}{\rho_1}},$$

where ρ_1 and ρ_2 are the internal and external radius of the gutta-percha sheath, λ and λ_1 the conductivities of it and the wire, $4\pi\mu = 1 + 4\pi k$ the constant of dielectricity of the gutta-percha. Therefore the velocity of propagation of the waves increases with the conductivity of the gutta-percha, simultaneously with which their height diminishes as they travel onwards. If the conductivity of the gutta-percha $\lambda = 0$, then becomes

Aug 78

$$a = \beta = \sqrt{\frac{n\mu}{\lambda_1 \rho_1^2 \log \frac{\rho_2}{\rho_1}}}.$$

If the wire is infinitely long, then (if, for $z = 0$, $\phi = \cos. n t$) is $\phi = e^{-\beta z} \cos. (n t - a z)$. Further, the following case is discussed: That the wire possesses the length l, but has its termination connected with one of the coatings of a condenser, the other side of which is led away to earth. For the calculation in question, as well as the rest of the working, which cannot well be given in abstract, we must refer the reader to the original memoir.—*Beiblätter zu den Annalen der Physik und Chemie.*

Earth Currents and Electrical Meteorology.—Mr. Richard Owen, writing from Indiana State University, Bloomington, Ind., gives an account of some tests with regard to the strength and direction of electrical currents in the earth's crust. He states that when a storm is approaching, the needle of his galvanometer is affected as long as twenty-four or even forty-eight hours before the storm arrives, and suggests that this should be taken advantage of in signal offices. He finds also that, when one wire is attached to earth and the other to a high lightning conductor, the current is from the air to earth, but, with a low conductor, the contrary is the result. Sept 78

The Variations in the Intensity of Currents Transmitted through Imperfect Contacts according to the Pressure Exerted between them.*—One of the most interesting modes of demonstrating the variations in the intensity of currents transmitted through imperfect contacts, according to the pressure exerted upon the latter, is to wind upon a glass tube a helix of copper wire (say No. 16), without any insulating covering, and then to fix to the ends of the tube an appliance for compressing the spirals. When this means is employed we observe that when the compression of the turns of wire, one against another, is very small, the resistance of the wire of the helix *is but little less than what it would be if the wire were completely covered with silk, and that this resistance constantly diminishes with the compression until the latter arrives at its maximum.* When the wire is bright the effect is less marked than when it is slightly oxidised; nevertheless, it is even then very appreciable; and since an inverse effect is produced when the compression is slackened, we cannot attribute this effect to a simple action of the layer of oxide which may have formed upon the wire. I had made the experiment in 1864, at the time when I laid before the Academie des Science the electro-magnets, with uncovered wire of M. Carlier instruments, which at that period attracted much attention in the scientific world, and which are, even in our days, advantageously employed in certain circumstances—for example, to avoid the sparks of the extra current. In 1865 I published a long memoir in the *Annales Télégraphique* on the effects produced with this interesting apparatus, and I even quoted the experiment above mentioned (see vol. viii., p. 211). I think we have not hitherto sufficiently considered the physical effects produced at the points of contact of conducting bodies traversed by a Aug 78

N, AUGUST 10, 1878.

current. There is positively a resistance to the passage, which varies with the pressure exerted upon the contact pieces. Is this effect to be accounted for on the hypothesis that the surface of contact may become better developed in consequence of this pressure, the action being equivalent to an augmentation of section in the conductors?—or should we attribute it to repulsions occurring between the contiguous elements of the same current, which, being effected with greater facility with slight contacts than with better contacts, would tend to be destroyed by the latter?—or, again, should they be ascribed to the molecular variations which produce sounds in microphones employed as receivers? Such are the ideas which occur to one whilst observing the phenomena, but these ideas require investigation, and to this point I would direct the attention of experimentalists.—Th. du Moncel.

* *La Correspondance Scientifique.*

ON THE RELATION BETWEEN THE ELECTROMOTIVE FORCE ACTING IN A VOLTAIC CIRCUIT, AND THE WEIGHT OF ZINC CONSUMED IN THE BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The question propounded by your correspondent "O. E. B." is somewhat indefinite, but merits, I think, a more accurate answer than it has hitherto received, since it involves points of very considerable theoretical and practical importance.

This question is stated as follows:—"Is not the increase of electromotive force of one battery over another obtained chiefly, if not entirely, by a more rapid consumption of zinc? Take, for example, a Grove and a Daniell; the former is said to have twice the power of the latter. Does it not consume twice as much zinc as the Daniell in each unit of time?"

To answer the particular question it is necessary to assume certain conditions which are not specified, as, for instance:—

1. The current is maintained constant;

Or, 2, the resistance of the circuit is constant.

Moreover, to answer the general question, we require to take one of the two following cases:—

(a). The total E.M.F. is increased by augmenting the E.M.F. of each couple in a battery of a given number of cells,

Or (b) the E.M.F. is increased by augmenting the number of cells in series.

Thus the one question resolves itself into four questions, the answers to which are as follow:—

I (a). The consumption of zinc is not increased by any augmentation of the E.M.F., although the current traverses a resistance necessarily increased in the same ratio as the E.M.F.

I (b). The consumption of zinc is increased proportionately to the E.M.F.

II (a). The consumption of zinc is increased proportionately to the increased E.M.F., or proportionately to the current.

II (b). The consumption of zinc is proportionate to the square of the ratio between the increased and the original E.M. Forces.

Mr. L. A. Davies—in the first sentence of whose communication the words, "If we wish to double the E.M.F." have evidently, by a *lapsus pennæ*, been written for "If we wish to double the current"—has taken the last case; and his answer, under the conditions specified, is correct.

In regard to Mr. A. C. M. Weaver's letter, I may state that I am answerable for the formula $Z = \frac{E^2 \times 16}{R}$ grains per hour, given by him, but not for its application to any battery other than Daniell's. The case taken by him is that indicated by 2 (a), and his answer is therefore incorrect.

My general formula for the consumption of zinc in a battery is the following:—

$$Z = \frac{E^2}{R e} \times 17{\cdot}3 = \frac{E}{R} n \times 17{\cdot}3 = \frac{I E}{e} \times 17{\cdot}3 = I n \times 17{\cdot}3,$$

Where Z = weight of zinc consumed, in grains per hour,
E = the total E.M.F in volts,
R = the resistance in ohms,
I = the current in Vebers per second,
e = the E.M.F. of each cell of the battery,
and n = the number of cells in the battery.

The economy—so far as regards the consumption of zinc—of employing cells of high E.M.F. is, perhaps, best seen in the case of a constant current through a constant resistance—*e. g.*, when a given current is obtained through a telegraph circuit with cells of lower and of higher E.M.F. In this case the consumption of zinc is inversely as the E.M.F. of each of the couples of which the requisite battery is made up; or, in other words, the economy of zinc is directly as the E.M.F. of the cell employed.

It may be useful to give an example of the application of the formula $Z = \frac{E}{R} n \times 17{\cdot}3$ *grains per hour* to the four cases specified above. According to the suggestion of "O. E. B.," I will take the Daniell and the Grove cells, and *suppose* that their electromotive forces are respectively 1 and 2 volts. Let our initial current be that of a battery of five Daniells in series acting through a total resistance of 100 ohms.

Here we have $E = 5$, $R = 100$, and $n = 5$.

The current is $\frac{E}{R} = \frac{5}{100} = {\cdot}05$, Aug 74.

and the weight of zinc consumed per hour will be:—

$$Z = {\cdot}05 \times 5 \times 17{\cdot}3 = 4{\cdot}32 \text{ grains.}$$

I. (a). Instead of the five Daniells, let us now use five Groves. We shall now have $E = 10$, $n = 5$, and, since $\frac{E}{R}$ must be ·05, $R = 200$.

Thus $Z = \frac{10}{200} \times 5 \times 17{\cdot}3 = 4{\cdot}32$ grains per hour.

I. (b). Let us now double the initial E.M.F. by doubling the number of Daniells' cells in series. We shall have

$$E = 10,\ R = 200,\ n = 10,\ \frac{E}{R} = {\cdot}05, \text{ and}$$

$$Z = \frac{10}{200} \times 10 \times 17{\cdot}3 = 8{\cdot}65 \text{ grains per hour.}$$

II. (a). Using five Groves through the initial resistance of 100 ohms, we have

$$E = 10,\ R = 100,\ n = 5,\ \frac{E}{R} = {\cdot}1, \text{ and}$$

$$Z = \frac{10}{100} \times 5 \times 17{\cdot}3 = 8{\cdot}65 \text{ grains per hour.}$$

II. (b). Lastly, with ten Daniells acting through the initial resistance of 100 ohms, we have

$$E = 10,\ R = 100,\ n = 10,\ \frac{E}{R} = {\cdot}1, \text{ and}$$

$$Z = {\cdot}1 \times 10 \times 17{\cdot}3 = 17{\cdot}3 \text{ grains per hour.}$$

The last value equals $4{\cdot}32 \times 4$—*i. e.*, the original consumption of zinc multiplied into the square of the ratio $\frac{10}{5} = 2$ of the increased to the initial E.M.F.

DESMOND G. FITZGERALD.

Electrician Sept 78

IS ELECTRICITY LIGHT?—This rather startling statement was the heading of a letter recently appearing in a contemporary, but still we doubt if the fact is proved. Scepticism is natural, even when the experiments of Professors Ayrton and Perry give equivalent velocities to Light and Electricity. We may be on the high road to discover what electricity is, and give such proofs as will generally be accepted by scientific men, but as yet eminent men are undecided as to the answer of the question, What is Electricity? M. Rotti and others have attempted to attribute it to ether currents, and, if we are not mistaken, Mr. Preston not only imagines one great ether system, but he would have two, or, if required by the exigencies of his theories, three or thirty. M. Edlund differs, to a certain extent, from MM. Rotti and Herwig, but he theorises that electricity is identical with the luminiferous ether.

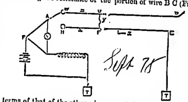
TERRESTRIAL INFLUENCE ON POLARISATION OF LIGHT.—In the course of his researches on rotary magnetic polarisation, Henri Becquerel has been led to the direct estimate of the action of terrestrial magnetism upon different bodies. In the course of these experiments he has found that if a tube, containing bisulphide of carbon, is placed between a polariser and an analyser, in the plane of the magnetic meridian, there is an angular difference of 6·5′ between the two positions of the plane of polarisation when looking towards the south or towards the north. This difference he attributes to terrestrial action.—*Comptes Rendus.* Sept 78

59

DETERMINATION OF A POINT OF CONTACT BETWEEN TWO WIRES.

The formula for the localisation of a contact between telegraphic wires previously given in this journal (see *Electrician* July 20th), in addition to the simplicity of its application, has the merit of being independent of the diameter of the wires.

Expressing the resistance of the portion of wire B C (Fig. 1)*



in terms of that of the other wire, we get the two equations:

$$R = m x + y + L - x,$$

$$r = \frac{(m x + y) x}{m x + y + x} + L - x.$$

If in this latter we substitute the value of y obtained from the first equation, the quantity $m x$ is eliminated, and we have

$$r = \frac{R x - L x + x^2}{R - L + 2x} + L - x,$$

which, simplified as before, becomes

$$x = L - r + \sqrt{(L - r)(R - r)},$$

where x is the resistance of the length of wire between the station whence the experiment is made, and the fault, referred, therefore, always to the wire which has its further extremity put to earth.

It can also be demonstrated that the above formula is independent of the diameter of the wires in contact if we take the two resistances B C and y as a single one. Working out the calculations, we arrive at the same result. Yet another method might be adopted with advantage, which is expressed in a formula even more simple than the first, but it has the drawback of necessitating the alteration of one of the communications at the distant stations. The following explains this second method:—

The resistance B C F E is measured as before, and results in $R = L + y$. The further extremity of the wire H E is then also insulated, and the communications being disposed as shown in the cut, the resistance of the complete circuit B C F H is taken. This will be expressed by $r = 2x + y$. Subtracting from this last the former resistance, we obtain $r - R = 2x - L$; and thence $x = \frac{L + r - R}{2}$.

From this formula we at once perceive that, if $r = R - D$, $x = \frac{L}{2}$, or, in other words, that the fault is half way down the line. If $r > $ or $< R$, the point of contact is respectively beyond or before the middle of the line.

The general formula of Schwendler for determining the distance of a contact between two wires of different diameters is as follows:—

$$x = \frac{r - \sqrt{(L m + L' m' - r)(R - r)}}{m + m'}$$

where L is the length in miles of one of the wires, m its resistance per mile, L' the length of the other wire, m' its resistance per mile, r the resistance of the complete circuit when the two wires are insulated at the further extremities, and R the resistance of this circuit when the two further extremities are united. This method of Schwendler has the advantage of not comprising the earth within the circuit, but it cannot be expressed in a simple form.—F. CARDARELLI, in the *Elettricista*.

---

* In this diagram, for Fig. 1 A H should be joined by a dotted line; for Fig. 2 the earth-plates T should be removed.

advantageous for correspondence from Lisbon to St. Petersburg, or from Dublin to Constantinople, still would not increase these messages much where the telegraphing community is not numerous. It would, however, sensibly diminish the traffic between adjoining or near states to the detriment of the numerous relations between these countries. This grave inconvenience would involve without doubt the maintenance of the reduced taxes already applied between them, and then the system, while ceasing to be uniform, would become ruinous for great distances without compensation in the nearer relations. One understands, then, why this proposition was discarded for a long time to come.

A higher tax is justified beyond a certain distance by the single fact that the telegram has a much higher value for correspondents. It is equally justified when greater promptitude (priority of transmission) or other special advantages are obtained.

These higher charges constitute the only means of preserving a reduced tariff for short distances, and for ordinary correspondence.

[TO BE CONTINUED.]

NOTE ON THE THEORY OF ELECTRIC ABSORPTION.

BY H. A. ROWLAND, C.E.

In experimenting with Leyden jars, telegraph cables, and condensers of other forms in which there is a solid dielectric, we observe that, after complete discharge, a portion of the charge reappears, and forms what is known as the residual charge. This has generally been explained by supposing that a portion of the charge was conducted below the surface of the dielectric, and that this was afterwards conducted back again to its former position. But, from the ordinary mathematical theory of the subject, no such consequence can be deduced, and we must conclude that this explanation is false. Maxwell, in his "Treatise on Electricy and Magnetism," Vol. 2, Chap. X., has shown that a substance composed of layers of different substances can have this property. But the theory of the whole subject does not yet seem to have been given.

Indeed, the general theory would involve us in very complicated mathematics, and our equations would have to apply to non-homogeneous crystalline bodies, in which Ohm's law was departed from, and the specific inductive capacity was not constant. We should, moreover, have to take account of thermo-electric currents, electrolysis, and electro-magnetic induction. Hence, in this paper I do not propose to do more than to slightly extend the subject beyond its present state, and to give the general method of still further extending it.

Let us at first, then, take the case of an isotropic body in general, in which thermo-electric currents and electrolysis do not exist, and in which the changes of currents are so slow that we can omit electro-magnetic induction. The equations then become*

$$\frac{d}{dx}\left(\kappa\frac{dV}{dx}\right)+\frac{d}{dy}\left(\kappa\frac{dV}{dy}\right)+\frac{d}{dz}\left(\kappa\frac{dV}{dz}\right)+4\pi\rho=0,$$

$$\frac{d}{dx}\left(k\frac{dV}{dx}\right)+\frac{d}{dy}\left(k\frac{dV}{dy}\right)+\frac{d}{dz}\left(k\frac{dV}{dz}\right)-\frac{d\rho}{dt}=0,$$

in which κ is the specific inductive capacity of the substance, K the electric conductivity, V the potential, ρ the volume density of the electricity, and t the time. The subtraction of one equation from the other gives

$$(1)\quad \frac{dV}{dx}\frac{d}{dx}\left(\log\frac{k}{\kappa}\right)+\frac{dV}{dy}\frac{d}{dy}\left(\log\frac{k}{\kappa}\right)+\frac{dV}{dz}\frac{d}{dz}\left(\log\frac{k}{\kappa}\right)-\frac{1}{k}\frac{d\rho}{dt}-\frac{4\pi\rho}{\kappa}=0.$$

To introduce the condition that there shall be no electric absorption, we must observe that, when that phenomenon exists, a charge of electricity appears at a point where there was no charge before; in other words, the relative distribution has been changed. Hence, if the relative distribution remains the same, no electric absorption can take place. Our condition is then $\frac{\rho}{\rho'}=c$, where c is independent of t, and ρ and ρ' are the densities at the points x, y, z, and x', y', z'. This gives $\frac{d}{dt}\left(\log\frac{\rho}{\rho^0}\right)=0$,

$$(2)\quad \ldots \quad \text{or } \frac{1}{\rho}\frac{d\rho}{dt}=\frac{d}{dt}\left(\log\frac{\rho}{\rho^0}\right)=-c,$$

where c is a function of t only, and not of x, y, z, and ρ^0 is the equal of ρ at the time $t=0$. As we have

$$\frac{1}{m}\frac{dV}{dn}\frac{dm}{dn}=\frac{dV}{dx}\frac{d}{dx}\left(\log\frac{k}{\kappa}\right)+\frac{dV}{dy}\frac{d}{dy}\left(\log\frac{k}{\kappa}\right)+\frac{dV}{dz}\frac{d}{dz}\left(\log\frac{k}{\kappa}\right),$$

where $m=\frac{k}{\kappa}$ and n is a line in direction of the current at the given point, equation (1) becomes

$$\frac{1}{m}\frac{dV}{dn}\frac{dm}{dn}-\frac{1}{k}\frac{d\rho}{dt}-\frac{4\pi\rho}{\kappa}=0.$$

From equation (2) $\rho=\rho^0\epsilon^{-\int_0^t c\,dt}$, and hence

$$\frac{1}{m}\frac{dV}{dn}\frac{dm}{dn}+\rho^0\epsilon^{\int_t^0 c\,dt}\left(\frac{c}{k}-\frac{4\pi}{\kappa}\right)=0.$$

If we denote the strength of current at the point S, we have $S=-k\frac{dV}{dn}$, and

$$(3)\quad \ldots \quad \frac{1}{cm-4\pi m^2}\frac{dm}{dn}=+\frac{\rho^0}{S}\epsilon^{\int_t^0 c\,dt};$$

this equation (3) gives the value of $\frac{k}{\kappa}=m$ at all points of the body and at all times, so that the phenomenon of electric absorption shall not take place. As this equation makes m a function of x, y, z, s, and t, the relation in general is entirely too complicated to ever apply to physical phenomena without some limitation. Firstly, then, as c is only an arbitrary function of t, we shall assume that it is constant:—

$$\therefore\quad \frac{1}{cm-4\pi m^2}\frac{dm}{dn}=+\frac{\rho^0\epsilon^{-ct}}{S}.$$

The most important case is where m is a constant; then $\frac{dm}{dn}=0$ and $c=4\pi m$, $S=S_0\epsilon^{-ct}$, $\rho=\rho^0\epsilon^{-ct}$.

In this case, therefore, we see that both the electrification and the currents die away at the rate c. The case where Ohm's law is true and the specific inductive capacity is constant is included in this case, seeing that, when k and κ are both constant, their ratio m is constant. But it also includes the cases where k and κ are both the same functions of V, S, or x, y, z, seeing that their ratio m would be constant in this case also.

When m is not constant, the chances are very small against its satisfying equation (4).

Hence, we may in general conclude that electric absorption will almost certainly take place unless the ratio of conductivity to the specific inductive capacity is constant throughout the body.

This ratio m may become a variable in several manners, as follow:—

1st manner.—The body may not be homogeneous. This includes the case which Maxwell has given, where the dielectric was composed of layers of different substances.

2nd manner.—The body may not obey Ohm's law; in this case k would be variable.

3rd manner.—The specific inductive capacity κ may vary with the electric force.

It is to be noted that the cases of electric absorption which we observe are mostly those of condensers formed of two planes, or of one cylinder inside another, as in a telegraph cable. Our theory shows that different explanations can be given of these two cases.

The case of parallel plates does not admit of being explained except on the supposition that m varies in the first manner above given, or in this manner in combination with the others, for we can only conceive of the conductivity and the specific inductive capacity as being functions of the ordinate or of the electric force. As the latter is constant for all points between the plates, m would still be constant, although it were a function of the electric force, and thus electric absorption would not take place.

We may, then, conclude that, in the case of parallel plates, omitting explanations based on electrolysis or thermo-electric currents, the only explanation that we can give at present is that which depends on the non-homogeneity of the body, that is the case which Maxwell has given in the form of two different materials. Our equations show that the form of layers is not necessary, but that any departure from homogeneity is sufficient. It is to be noted that the homogeneity which we speak of is electrical homogeneity, and that a mass of crystals with their axes in different directions would evidently not be electrically homogeneous, and would thus possess the property in question. In the case of glass it is very possible that this may be the case

* "Maxwell's Treatise," Art. 325.

ELECTRIC DISCHARGE IN GASES

I.

IN a paper read some time since at the Royal Society,[1] Drs. Warren De La Rue and Hugo W. Müller gave the first part of an account of their researches on the electric discharge in gases. This part, of which we shall at present give some account, consists mainly of a description of the apparatus employed in this research, and of the results of their experiments with gases at atmospheric pressure and pressures down to 141 millimetres. They have since communicated to the Royal Society a second part, which treats of the discharge in highly rarefied gases (vacuum tubes).

The source of electrification used by Messrs. De La Rue and Müller was a battery of chloride of silver elements; commencing with 1,000, the authors have from time to time increased the number of cells to 11,000 joined in series (11,330 volts). In spite of its containing a somewhat costly material, this element, when compared with the many other forms of voltaic cell at present in use, possesses points of advantage such as render its general adoption extremely probable; we therefore transcribe in considerable detail the authors' description of it in its present improved form.

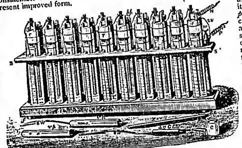


Fig. 1.—Nest of Cells.

Fig. 1 shows a nest of twenty cells of the most recent construction; the several components of the cells are given separately at the base of the stand. The glass tube T is 5½ inches high, and 1⅛ inch in diameter: it has a flat bottom. The stopper *c* is of paraffin, and is perforated with two holes, one for the zinc rod (*z*) to pass through, the other for letting in the liquid; the latter is ultimately closed with a paraffin plug (*pp*). Cork and india-rubber stoppers were tried and abandoned. The zinc is obtained of the Belgian Vieille Montagne Company. When it is intended to keep a battery more than a year in action the zincs should not be amalgamated, as the silver wires in contact with them would gradually be rotted through. Platinum, which would not become amalgamated, might have been substituted for the silver wires; but it would have cost 55*l.* extra per 1,000 cells. The zinc rods are 15 cm. long, 0·56 cm. in diameter, and perforated at the top with a hole 0·25 cm. in diameter. The chloride of silver (AgCl) is cast in the form of a rod on a flattened silver wire S W; the rods are 5·4 cm. long, 0·762 cm. in diameter, and weigh 12·97 grms. The silver wires are 20 cm. long, 0·127 cm. wide, and 0·0229 cm. thick, weighing 0·88 gms. each; they protrude slightly beyond the bottom of the rod of chloride, as will be seen from the figure. The wires and rods were obtained from Messrs. Johnson and Matthey, of Hatton Garden; the cost, including labour of casting, amounted to 2*s.* per cell. *v p* is a cylinder of three folds of vegetable parchment; at its lower end the folds are stitched together with thread, and at the upper part they are interlaced with the silver wire, and thus prevented from unfurling. The object of the parchment cylinder is to prevent the reduction of the chloride of silver rod, which would result from its accidental contact with the zinc. By giving proper bends to the silver wire before making up the cell it is easy to cause the chloride rod to lie vertically and press gently against the glass wall.

The liquid used for the cells is a solution of chloride of ammonium, 23 gms. to 1 litre of distilled water; by making use of a glass siphon with a long arm of india-rubber tubing, provided with a pinch cock, and terminating in a glass tube drawn down to enter freely into the hole in the paraffin stopper, it was found that 2,400 cells could be charged by one person in ten hours.

In making up a battery the glass cells are first arranged in their nests; next the paraffin stoppers are fitted with zincs; then the chloride rods are inserted and the cell closed with the stopper, the thin silver wire passing between the glass and the paraffin. When these operations have been performed for all, the cells are joined up by passing the silver wire of each cell through the hole in the zinc rod of its neighbour, and securing it there by pressing in a taper brass plug *p* with a pair of pliers. Ultimately, the cells having been charged with fluid, as already described, and closed by the insertion of *p p*, a hot iron is run round the outside of the stopper and round the zinc rod to secure the latter in its place, and make tight the joints by the melting and re-setting of a little paraffin.

Thus set up, the battery has an electromotive force of about 1·03 volt and internal resistance of not more than 5 ohms per cell: the former remains remarkably constant, but the latter increases, especially in cells that are left long idle. This rise in internal resistance is caused by a skin of oxychloride of zinc, which gradually forms on the zincs in all batteries where the zincs are immersed in a neutral chlorine compound. The battery may be restored to its original resistance by removing and scraping the zinc rods, but a more expeditious mode is to withdraw the small paraffin plug used to close the hole in the stopper through which the cells are charged, and to introduce into each cell, containing 50 c.c., 1 c.c. of pure hydrochloric acid, sp. gr. 1·16, containing 31·8 per cent. HCl gas, equivalent to 0·3689 gm. acid. Before introducing it into the cells, as is conveniently done by means of a graduated pipette furnished with a stop-cock, it is better to dilute the acid with an equal volume of distilled water. An effervescence takes place, and it is therefore necessary to allow the tubes to remain open twenty-four hours before the small paraffin plug is replaced, in order to permit the hydrogen, which is generated, to escape. It required two days for one person to perform this operation on a battery of 1,200 cells. The acid dissolves 0·3295 gm. of zinc or its equivalent of oxide.

After having been in almost daily use on circuits comparable with those occurring in overland telegraphy, it was found that in two batteries the amount of AgCl reduced in sixteen months averaged 4·57 gms. per cell, while in two other batteries which had been worked for ten months the reduction amounted to 3·57 gms. per cell.

An accident enabled the authors to give precise information as to the loss in working up the reduced silver; 600 cells having been accidentally allowed to run

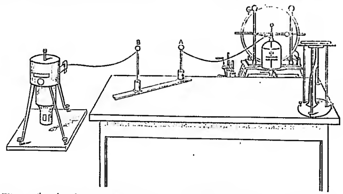
THE DISRUPTIVE DISCHARGE OF ELECTRICITY[1]

BY means of the following method we have been able to investigate the laws of the disruptive discharge of electricity of high potential—a subject of investigation which is the complement of that in which Drs. Warren de la Rue and Müller have been simultaneously engaged. In making these experiments I have had the able co-operation in succession of Messrs. Salvesen, Connor, Stewart, Simpson, and Playfair.

The method essentially consists in connecting the prime conductor of the Holtz machine, not with the electrometer directly, but with an insulated spherical ball placed at some distance from an equal spherical ball, the latter being connected with the electrometer. The woodcut represents, *in situ*, the apparatus which was used in the case of the gases. The receiver of the air-pump, which has a rod capable of moving air-tight, was attached to one of the conductors of the Holtz machine in such a manner that the conductor and the rod formed one conducting system. Projecting from the plate of the air-pump was a short metal rod, which formed one conductor with the metallic parts of the air-pump, and, by means of a wire, with the uninsulated conductor of the Holtz machine. Electrodes of various forms were made to screw on to the ends of the rods. Of the two insulated brass balls one, A, was fixed; the other, B, could be moved along the connecting board. The wire joining A to the collar of the receiver is insulated with gutta-percha. The electrometer in connection with B is one of Sir W. Thomson's divided ring reflecting electrometers.

When the potential of A is raised by driving the machine, the potential of B is also raised, and this goes on until a discharge takes place between the electrodes inside the receiver. Hence the maximum deflection of the spot of light from zero is an indication of the difference of potential of the two surfaces between which the spark passed immediately before the discharge. By breaking the contact between the conductors of the Holtz machine before beginning to turn the wheel, and, by turning slowly and uniformly, we were able to make the image of the



wire move up continuously, and to be at rest at the instant of discharge. After the discharge took place the image fell back to zero, or a point near zero. We always noted the position taken up by the image when the conductor of the machine was completely discharged.

The force resisting the deflection of the mirror is the action of two external magnets upon several small magnets fixed to the back of the mirror.[2]

One great merit of our method is the rapidity with which observations can be made. Three readings were in general taken for each entry. The mean of these is very probably free from any error due to accidental variations in the passage of the spark. An extensive series of observations have been printed in full in the *Transactions* of the Royal Society of Edinburgh. The following are the more important results:—

A spark was taken through air between plates at a constant distance, and the distance between the balls A and B varied. Let V denote the induced potential, and r the distance between the centres of A and B; then the experimental curve obtained satisfies the equation—

$$V = 6081r^{-1} - 42{\cdot}26$$

for values of r greater than 24 centimetres; but for less values of r the function requires to be corrected by being multiplied by—

$$\cdot 524 + \cdot 02r.$$

Sparks were taken through air at the atmospheric pressure between parallel metal disks of 4 inches diameter for distances up to 1·2 centimetres. The function for V, the difference of potential in terms of s, the length of the spark is—

$$V = 66{\cdot}94\sqrt{(s^2 + \cdot 205s)},$$

[1] Abstract by the author of thesis for D.Sc. and other papers printed in the recently issued part of the *Transactions* of the Royal Society of Edinburgh. By Alexander Macfarlane, M.A., D.Sc.

[2] Our results were reduced to absolute measure by means of the absolute electrometer represented on the table.

65

the equation of a hyperbola whose semi-transverse axis is ·1025 centimetres, and semi-conjugate axis 6·8623 C.G.S. units. From the above equation we infer that—

$$R = 66{\cdot}94\sqrt{\left\{1 + \cdot 205\frac{1}{s}\right\}}$$

where R denotes the electrostatic force; from which it is evident that as s becomes smaller R becomes greater. A similar curve was obtained when hydrogen was substituted for air.

When the disks were heated before taking the sparks, the curve obtained satisfies the equation—

$$V = 87{\cdot}04s - 19{\cdot}56s^2,$$

a parabola, from which we deduce—

$$R = 87{\cdot}04 - 19{\cdot}56s.$$

It was found that when the capacity of the charged conductor was changed, the difference of potential required to produce a spark remained constant.

When the discharge was continued so as to keep the spot of light at a fixed deflection, the reading was always less than for the corresponding single discharge, but the curves were similar.

Readings were taken of the difference of potential required to produce a ·5 centimetre spark through air at different pressures from the atmospheric to 20 mm. They give—

$$V = \cdot 0458\sqrt{\{p^2 + 203p\}}$$

where p denotes the pressure in millimetres of mercury.

The electric strengths of several gases were determined by comparing the differences of potential required to pass a ·5 centimetre spark through the gas at the atmospheric pressure.

Dielectric.	Electric Strength.		
	Macfarlane.	De la Rue and Müller.	Faraday.
Air...	1	1	1
Carbonic Acid ...	·95	1·06	·91
Oxygen	·93	1	·71
Hydrogen... ...	·63	·54	·53
Coal Gas	·93	—	·71

"Electric strength" is the term used by Prof. Clerk-Maxwell to denote the physical constant in question. I have added, for the sake of comparison, values deduced from the results of De la Rue and Müller and of Faraday, but the ratios given do not strictly give the relative electric strength, but the ratio of the lengths of spark when the difference of potential is kept constant.

The difference of potential required to produce a spark between two spherical balls is approximately proportional to the square root of the length of the spark. This we have verified up to 15 cm.

On proceeding to investigate the discharge through insulating liquids, we first took up oil of turpentine. The liquid was placed in a glass jar of 7 inches diameter and 5 inches height. A screw passing through the bottom of the jar served to fix the lower electrode, and also to afford conducting connection with the earth. We observed four modes of discharge: by means of threads of solid particles, by motion of the liquid, by a disruptive discharge, and by motion of gas bubbles. When a chain was formed the index of the electrometer behaved as if a current were passing. The discharge, when sufficiently great, broke the thread and turned into a spark. The liquid was more easily set in motion when its surface was not much higher than the upper plate. The bubbles of gas appeared to be formed by the passing of the spark. They were always attracted to the negative electrode. When the electrification was neutralised they of course adhered to the under surface of the upper disk; when the disk was electrified negatively they still adhered; when positively they were repelled so as to remain suspended in the liquid or to adhere to the lower electrode, according to the greater or less distance between the electrodes. At a diminished pressure the bubbles produced at the upper surface were observed to effect the discharge by carrying the electricity with them to the negative electrode. The fact that it is possible to cause a shower of electrified bubbles to descend and produce a flash and sound on impinging on the lower surface appears to throw some light upon the nature of lightning balls.

Similar phenomena were observed in paraffin oil, excepting that the gas bubbles produced were generally attracted to the positive surface.

We observed the differences of potential required to pass a spark through paraffin oil and oil of turpentine between plates for distances up to ·5 cm. It was impossible to observe for greater distances, as our insulated wire allowed the charge to escape. For paraffin oil,

$$V = 750s - 15;$$

therefore,

$$R = 750.$$

The above has not been reduced to absolute measure. Thus R is constant in the case of the liquids, but variable in the case of the gases.

Electric Strength of Liquid Dielectrics

Air	1
Paraffin Oil (kind used for burning)	4
Oil of Turpentine	3·7

Sparks were taken between two platinum wires placed at right angles to one another. When one of the wires was heated by a voltaic current the electrometer deflection was diminished by about one-fourth of its amount.

We have also investigated the effect upon the electric spark of heating the air round the disks, the pressure being kept constant. The deflections of the electrometer for a constant spark for temperatures from 20° C. to 280° C. indicate a curve which slopes down gradually as the temperature is increased, while the deflections during cooling give a curve which is somewhat lower at the lower temperatures.

These experiments were made in Prof. Tait's laboratory, to whom we are indebted, not only for the use of apparatus, but also for ever ready advice.

which the greatest part of the Berlin press has assumed with regard to the doctrine of evolution must be attributed to this authority. But much as we must regret the reactionary current in this and other intelligent Berlin circles, yet we must point out that by this evil we are guarded from a far greater one. This greater, indeed the greatest, evil which could befall German science would be a Berlin 'monopoly of knowledge,' the *centralisation of science*. What highly disastrous fruit this centralisation has borne in France, for instance; how the Paris 'monopoly of knowledge' causes a constant degradation of French science, and has led it downwards from the greatest heights for the last half-century, is well known. Probably the wide-spread differentiation and the many-sided individuality of the German national spirit, the often-decried German particularism, will save us from a centralisation of science of this kind, which particularly in our capital, Berlin, would be doubly dangerous. Little as our 'small states' could be politically of any duration or could lead to a useful state-form, they have certainly been most beneficial and fertile for German science. Because this owes its principal advantages over others to the numerous little centres of education, which the capitals of the German small states formed, and to the many little universities which were always in healthy competition with one another. Let us hope that this beneficial decentralisation of science in our politically united Fatherland will continue permanently. Next to the centrifugal striving of our German national spirit, nothing will further this object so much as an energetic resistance to the free progress of science, just as now again it begins to show itself in the capital of the empire. Because at the same rate as this will remain behind in the mighty current of free and unimpeded mental progress, other numerous centres of education in Germany which follow this current enthusiastically, or at least willingly, will outrun it."

"If Emil Dubois Reymond wanted to make his 'Ignorabimus' the watchword of science, and Rudolf Virchow his still further-reaching 'Restringamur,' then from Jena and from a hundred other educational centres they are met with the call—

"*Impavidi progrediamur!*"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

STUDENTS of Natural Science who would much rather know French and German than Greek will be glad to learn that a very strong memorial against the retention of Greek as a subject for all honour candidates has been presented to Cambridge University. It is signed by ten heads of public schools, including Drs. Hornby (Eton), Butler (Harrow), and Abbott (City of London), Messrs. Matthew Arnold, Carlyle, W. E. Forster, the Bishops of Exeter and Manchester, Dean Cowie, Dean Stanley, and Dr. Vaughan, Prof. Jebb, and Mr. Roby, to say nothing of such bulwarks of science as Mr. Darwin, Prof. Huxley, Sir Joseph Hooker, Mr. Spottiswoode, and Prof. Tyndall.

THE Board of Musical Studies at Cambridge have applied for the appointment of a University Reader in Acoustics.

THE sum in the hands of the Sedgwick Memorial Committee for the erection of a new building for the geological collection is 12,000*l.*, not 1,200*l.* as we stated last week.

King's College (London) *Magazine*, No. 5, vol. ii. of which has been sent us, contains some pleasant reading, but no one would infer from its contents that the College was an important centre of scientific instruction and research.

DR. J. COSSAR EWART has been appointed by the Crown to the Chair of Natural History in the University of Aberdeen.

MR. F. GUTHRIE, formerly of Graaf-Reinet College, has been appointed to the Chair of Mathematics at the South African College, Capetown.

THE *Journal de St. Pétersbourg* gives the following particulars concerning the public provision for education in Russia:—The sum assigned in the Budget of this year for education is 15,971,289 roubles (about 2,395,000*l.*). There are eight Universities (not reckoning that of Helsingfors for Finland), with 5,629 students. Of these 83 are divinity students, 583 belong to the philological faculty, 1,629 to the faculty of law, 30 to that of Eastern languages, 622 to the mathematical faculty, 550 to that of natural science, and 2,130 to the medical faculty. There are 53 ecclesiastical seminaries, with 12,227 pupils; 195 gymnasia and pro-gymnasia, with 50,701 pupils; 56 middle-class schools, with 10,888 scholars. There are 19 military gymnasia, but the number of pupils is not given. For females there are 223 gymnasia and pro-gymnasia, having 34,878 pupils; and this does not include the many institutions which are subject to the control of the Fourth Division of the Imperial Chancellery. There are 68 normal schools and training colleges for teachers, having 4,968 students. There are 10 other such institutions supported by non-public funds. The number of elementary schools in operation this year is 25,491, with 1,074,559 pupils.

Royal Society, December 5.—"On the Illumination of Lines of Molecular Pressure, and the Trajectory of Molecules," by William Crookes, F.R.S., V.P.C.S.

Induction Spark through Rarefied Gases. Dark Space round the Negative Pole

The author has examined the dark space which appears round the negative pole of an ordinary vacuum tube when the spark from an induction coil is passed through it. He describes many experiments with different kinds of poles, a varying intensity of spark, and different gases, and arrives at the following propositions:—

Illumination of Lines of Molecular Pressure

a. Setting up an intense molecular vibration in a disk of metal by electrical means excites a molecular disturbance which affects the surface of the disk and the surrounding gas. With a dense gas the disturbance extends a short distance only from the metal; but as rarefaction continues, the layer of molecular disturbance increases in thickness. In air at a pressure of ·078 mm. this molecular disturbance extends for at least 8 mm. from the surface of the disk, forming an oblate spheroid around it.

b. The diameter of this dark space varies with the exhaustion; with the kind of gas in which it is produced; with the temperature of the negative pole; and, in a slight degree, with the intensity of the spark. For equal degrees of exhaustion it is greatest in hydrogen and least in carbonic acid, as compared with air.

c. The shape and size of this dark space do not vary with the distance separating the poles; nor, only very slightly, with alteration of battery power; nor with intensity of spark. When the power is great the brilliancy of the unoccupied parts of the tube overpowers the dark space, rendering it difficult of observation; but, on careful scrutiny, it may still be seen unchanged in size, nor does it alter even when, with a very faint spark, it is scarcely visible. On still further reduction of the power, it fades entirely away, but without change of form.

The author describes numerous experiments, devised to ascertain if this visible layer of molecular disturbance is identical with the invisible layer of molecular pressure or stress, the investigation of which has occupied him for some years.

The Electrical Radiometer

One of these experiments is as follows:—An ordinary radiometer is made, with aluminium disks for vanes, each disk coated with a film of mica. The fly is supported by a hard steel cup instead of a glass cup, and the needle point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer can therefore be connected with an induction coil, the movable fly being made the negative pole.

Passing over the phenomena observed at low exhaustions, the author finds that, when connected with the coil, a halo of a velvety violet light forms on the metallic side of the vanes, the mica side remaining dark throughout these experiments. As the pressure diminishes a dark space is seen to separate the violet halo from the metal. At a pressure of half a millimetre this dark space extends to the glass, and positive rotation commences.

On continuing the exhaustion the dark space further widens out and appears to flatten itself against the glass, and the rotation becomes very rapid.

When aluminium cups are used for the vanes, instead of disks backed with mica, similar appearances are seen. The velvety violet halo forms over each side of the cup. On increasing the exhaustion the dark space widens out, retaining almost exactly the shape of the cup. The bright margin of the dark space becomes concentrated at the concave side of the cup to a luminous focus, and widens out at the convex side. On further exhaustion the dark space on the convex side touches the glass,

THE ELECTRICITY OF THE TORPEDO[1]

II.

4. *CURRENTS induced by a torpedo discharge are all produced at the beginning of each wave. There are currents induced on the completion of a circuit,* i.e., *the inverse of the inducting currents, as is shown by the electrometer.*

Fig. 7 will show the arrangement of the experiment to prove that the torpedo's discharge in the inductive coil

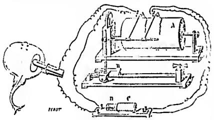

FIG. 7.

(D) produces, in the secondary coil (C) currents of sufficient energy to cause movement in the second signal placed in the circuit of the inducted coil. It must be remarked, however, that the electric apparatus which furnishes the indications of the passage of the discharge is not, as shown in the diagram, that which produces the inducted currents. Currents of sufficient intensity would not have been obtained to act upon the electro-magnetic signal, if we had opposed to the passage of the discharge a resistance so considerable as that of the coils of the electro-magnet. The difficulty has been averted by using the opposing apparatus for signalling; and this we are authorised in doing, since the discharges are absolutely symmetrical to the right and left when the nervous centres are excited by the magnet.

That exception made, let us examine the results of the experiment. The traces were placed one over another; one (as 1 in Fig. 8) indicating the successive waves of the discharge, and the other (as 2 in Fig. 8) the currents inducted by the waves. This figure already shows an important fact: that the number of inducted currents is equal to that of the inducting waves; and that each inducted current is produced at the commencement of each wave, just as in a galvanic current an inducted current is produced at each completion. But here we only find currents inducted by the completion or, more exactly, at the commencement of the waves; none are produced during the decreasing phase of each wave, or at least if they are produced they do not act upon the electro-magnetic signal.

From the preceding it should be inferred that the currents, inducted by the torpedo-waves and produced at the commencement of these waves, must in that be analogous to the inducted currents resulting from the completion of a galvanic circuit.

No instrument could be better than Lippmann's electrometer for giving us information as to the direction of the currents inducted by the torpedo waves. Its instantaneous action enables it to indicate, by a sudden displacement in a determinate direction, the direction of each inducted current.

If a weak current derived from the main discharge is passed through the electrometer, we see the column after moving to one side of the reticule always oscillate to the same side, thus showing that the successive waves are

FIG. 8.

joined one to another, so that there is never an absolute break in the current. In Fig. 9 the arrows show the oscillation of the column towards the right side.

If the induced currents are directed through an electrometer by the discharge which causes the column of the instrument to deviate to the right, the direction of oscillation is immediately reversed (Fig. 10).

The comparison of those two diagrams showing that the inducted current has a contrary effect to that of the inducting current, brings together the inducted currents of the torpedo and those obtained by completing a galvanic circuit. To be more exact, since the circuit which comprises the torpedo remains always complete, we shall say that the inducted currents are produced at the beginning of each electric wave of the animal. Thus the torpedo calls forth in each of its electric waves an initial inducted current and does not give a terminal inducted current. This conclusion goes to support what we learned from the wave-writing of the electro-dynamograph, viz., that the initial phase of each wave has a suddenly increasing intensity, whereas the terminal phase presents a gradual decrease.

5. *The discharge of the torpedo is analogous to muscular tetanus; every electric wave in the discharge corresponds to a muscular shock.*

In what precedes we have endeavoured to give an idea of the torpedo discharge from the nature of the successive acts which constitute it, insisting only upon points relating to experimental science and to the direct results of M. Marey's investigations.

We are now enabled to meet the question on higher ground and consider the electric function from a philosophical point of view, by classing it with the muscular function.

FIG. 9.

FIG. 10.

Let us first compare the elementary action of electric discharge to the elementary action of muscular contraction, *i.e.*, the electric wave to the muscular shock.

[1] Continued from p. 297.

The simple excitation of the remote end of an electric nerve produces a single wave, as the simple excitation of a motor nerve produces a single shock. In both cases, at the moment of the nerve-excitation produced in the neighbourhood of the electric apparatus or of the muscular apparatus, the amount of delay is sensibly the same, about seven-hundredths of a second. The electric wave, like the muscular shock, has a phase of increase and a phase of decrease; the former, as we have seen, is abrupt or sudden from one part to another; the decreasing phase is much more gentle. The same agents modify the wave and shock in the same manner; heat renders both these actions more speedy and more energetic up to a certain point at which both electric reaction and muscular reaction disappear; cold acts equally upon movement and electric action, rendering both more slow, more feeble, more extended, and at last extinguishes them when the temperature is lowered to about zero C.

FIG. 11.

In the complex muscular act which is called contraction, as in the electric act which constitutes the discharge, the elementary phenomena which we have just been comparing, the waves and the shocks are added on one to another in the same manner; they succeed each other with a rapidity so great that each has not time to complete all the phases before its successor is produced. The floor and the shock are interrupted during their decreasing period by a new wave or shock coming to join on its

FIG. 12.

effect to what remained of the preceding act. But, as there are imperfect muscular contractions, cases of tetanus where the shocks are not completely fused together, not being rapid enough in their succession, so in the same way certain electric discharges present a remarkable discontinuity, such that the elements of the perfect act are seen arranging themselves, the waves following each other with less rapidity, the shocks separated from each other by a larger interval of time.

Let us now compare the effects of fatigue upon muscular contraction and upon the discharge, as we have compared them upon the muscular shock and upon the electric wave; we shall see the two acts modified in the same direction. It is even possible to see the torpedo-wave and discharge gradually becoming extinguished, just as muscular shocks disappear under the influence of exhaustion. This gradual extinction of the electric waves is very evident in Fig. 11, obtained by means of the electro-dynamograph.

Poisons which act directly or indirectly upon the muscular function modify in the same manner the electric function. Thus strychnine, for example, which in a very special manner exaggerates the excito-motor power and that which might be termed the excito-electric power of nervous centres; a complex reaction, a muscular tetanus on one side and a real electric tetanus on the other, is produced in reply to a simple excitation, the mere touch of the skin, or a slight noise.

Fig. 12 shows a type of muscular strychnine contraction in the frog. Here we observe a diminution of intensity produced in the middle of the muscular tetanus between two maxima, one at the beginning and the other at the close.

In agreement with this characteristic phenomenon, the cause of which is unknown, we observe in torpedo poisoning by strychnine a weakening or interruption towards the middle of the discharge. Fig. 13 shows on line A A a type of this species of interruption which must be compared with that which we have just seen on the tracing of muscular tetanus.

We might still further extend the comparison of those two functions, the electric and the muscular, by study-

FIG. 13.

ing the action of other fishes, such as the *Gymnotus*, the electric ray, &c.; and by showing that the results are identical when heat and cold act upon muscular contraction and upon the discharge of the torpedo. The preceding paragraphs are sufficient to justify the functional assimilation which, let us hasten to say, is in accordance with the anatomical assimilation.

We shall only add that these identifications are of higher interest than curiosity; the more our knowledge of muscular phenomena and electric phenomena becomes perfected, the more enlightened is our knowledge of the motor nerves. Does the fact that a voluntary discharge of the torpedo is a complex act not prove that the voluntary contraction of the muscles is also a complex act? Very certainly, the comparison of the voluntary contraction of the muscles with the tetanic phenomena produced by electricity or by strychnine, the existence of a muscular sound during the contraction, the quivering or

two external magnets upon several small magnets fixed to the back of the mirror.[2]

One great merit of our method is the rapidity with which observations can be made. Three readings were in general taken for each entry. The mean of these is very probably free from any error due to accidental variations in the passage of the spark. An extensive series of observations have been printed

[1] Abstract by the author of thesis for D.Sc. and other papers printed in the recently issued part of the *Transactions* of the Royal Society of Edinburgh. By Alexander Macfarlane, M.A., D.Sc.

[2] Our results were reduced to absolute measure by means of the absolute electrometer represented in the table.

satisfies the equation—

$$V = 60 \cdot 81 r^{-1} - 42 \cdot 26$$

for values of r greater than 24 centimetres; but for less values of r the function requires to be corrected by being multiplied by—

$$\cdot 524 + \cdot 02 r.$$

Sparks were taken through air at the atmospheric pressure between parallel metal disks of 4 inches diameter for distances up to 1·2 centimetres. The function for V, the difference of potential in terms of s, the length of the spark is—

$$V = 66 \cdot 94 \sqrt{(s^2 + \cdot 205 s)}.$$

dissociation of the shocks which are produced under the influence of cold, all these seem arguments in favour of the theory which considers muscular contraction as the result of very frequent shocks; but the complexity of the voluntary discharge of the torpedo, the manner in which the waves composing it succeed each other and are added together, forms a very important confirmation of the numerous presumptions already made.

FRANCOIS FRANCK

SCIENCE IN LANCASHIRE AND CHESHIRE

AT Liverpool the annual associated *soirée* of the Literary, Scientific, and Art Societies, eighteen in number, of which twelve are scientific, held at St. George's Hall on the 31st, was a marked success, and will tend much not only to foster scientific tastes in this district, but inculcate an element of scientific co-operation, in the various institutions of the town, that will be of the highest practical value. The fourteenth Winter Course of Free Lectures for the People, given at the Free Library and Museum, by order of the Corporation, commenced on the 6th of last month. Amongst the forty-one lectures announced, thirteen are on scientific subjects, given by the Rev. W. H. Dallinger, Mr. Moore (Curator), Mr. De Rance, Rev. H. H. Higgins, and others. The Liverpool Geological Society is also doing good work; a valuable paper on the carboniferous limestone of Denbighshire was lately read by Mr. Morton, and a short but important mineralogical paper was given by the President, Mr. Semmons. Geological knowledge has been increased by a boring at Bootle, sunk to determine the water-bearing properties of the new red sandstone at great depths, by Messrs. Mather and Platt, for the Liverpool Corporation, who were urged to this course by Alderman Bennett. The boring has reached a depth of 1,300 feet, is 25 inches in diameter, is filled with water up to a height of 50 feet from the surface, and, according to Messrs. De Rance and Morton, has proved the pebble beds of the Bunter to reach the extraordinary thickness of 1,200 feet, and the existence of the lower mottled sandstone beneath. The pumps not yet being fixed, it is impossible to judge how far the well will add to the supply of 6,000,000 gallons a day at present pumped from the corporation wells.

At Wigan, in addition to the ordinary course of lectures given at the Mining and Mechanical School, a special course has been arranged for candidates for colliery managers' certificates, and gives to the teaching of the school a special technical direction. The extension scheme for turning the very numerously attended evening classes of this school into a Mining Collegiate Centre for Lancashire, has necessarily languished under the unexampled and continued depression in the coal trade, though from the number and extent of the promised subscriptions and donations to the building-fund, there can be little doubt that, when better times again visit this country, this school will develop into an important centre of technical education. The town has lately had the good fortune to have presented to it a magnificent library, stored in a handsome building erected for the purpose, the former being the bequest of the late Mr. Winnard, the latter the gift of Mr. Thomas Taylor. The reference library is well stored with standard scientific works in all branches, and the selection reflects great credit on the industry and acumen of Mr. Gerrard Finch, barrister-at-law, who selected them, under the terms of the will. Some important works are of course conspicuous by their absence, but doubtless this will soon be remedied. The reference portion of this library will henceforth be opened on a Sunday to readers who have asked for special tickets, the extra cost of assistants being defrayed for three years by Mr. Taylor, the donor of the building. This town has also now a flourishing Literary and Scientific Society, with Lord Lindsay as president; it is divided into botanical, microscopical, and other sections, at which papers are read by the members, and discussed, and, in addition, special lectures are given to the united sections; amongst those delivered have been "Spectrum Analysis," by Lord Lindsay, and "Local Geology," by Mr. de Rance: others are announced by Prof. McKenny Hughes and Prof. Rudler.

At Southport there is at present little done for fostering a taste for either technical or scientific education, but the very fine aquarium is maintained in great efficiency, the contents of the table tanks, to which we have previously referred, being especially beautiful.

At Preston, meetings of the Scientific Society have been numerously attended, and the president, Dr. Arminson, and others, do good microscopical work. The meetings are held at the Avenham Institution, which is well filled with scientific works, including the natural history library of a defunct Naturalists' Society, and it is a matter of regret that the town, in adopting the Free Libraries Act, should not have carried out an amalgamation scheme, instead of running a new and inefficient library in opposition to the existing useful and self-supporting institution. The Gilchrist Trust lecturers here and at Burnley have been listened to with much interest by large audiences; and at the latter place Prof. Boyd Dawkins has inoculated his hearers with his taste for cave-hunting investigations, and searches have been organised into the wild hills which fringe the county boundary of Lancashire and Yorkshire, and form the backbone of England, a district which for the most part appears to be above the level of the glacial sea deposits.

At Chester the flourishing Natural Science Society that looks back with pride to Kingsley, its founder, and forward with hope to its president, Prof. McKenny Hughes, is divided into several sections like a small British Association. The most noticeable paper read was one by Mr. Shrubsole, on the Fenestellæ of the carboniferous limestone, which was an important and valuable contribution to our knowledge of this group, proving from perfect specimens that several supposed species are, in fact, portions of the same organism. General lectures have been given to the united sections by Prof. Judd and Mr. De Rance, who opened the winter session. The Society possesses a very good local museum, but unfortunately it is exhibited in the disused ball-room of an ancient hotel in an out-of-the-way part of the city, and is known to few of the scientific visitors of Chester, and is but seldom visited by the inhabitants. The collection would, however, form an admirable nucleus of a museum for teaching purposes, should the Corporation ever recognise the need of technical education in this town, and erect a building to hold a library, museum, and science and art schools by the side of their fine town hall. Towards filling museums of this class, great advantage would accrue if the duplicate specimens at the British and Jermyn Street Museums were either given, or allowed to circulate, in the same manner as the art treasures from South Kensington Museum. For valuable as are *local* collections for the scientific *specialists*, no one can doubt the importance of giving wide and varied knowledge to the general public, such as, perhaps, can only be imparted by the inspection of typical specimens of the natural and artificial products of all countries. Such a collection may be seen on a small scale in the admirable little museum at Castleton, in Derbyshire, formed by Mr. Rooke Pennington, which at once furnishes the visitor with all that can be collected for forming a mental local picture of the past, and affords the inhabitants of the district an opportunity of knowing something of the world around them.

At Manchester the museum at Owens College now includes the entire collections of the Manchester Natural

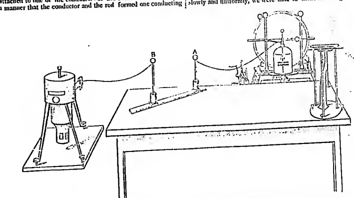
THE DISRUPTIVE DISCHARGE OF ELECTRICITY[1]

BY means of the following method we have been able to investigate the laws of the disruptive discharge of electricity of high potential—a subject of investigation which is the complement of that in which Drs. Warren de la Rue and Muller have been simultaneously engaged. In making these experiments I have had the able co-operation in succession of Messrs. Salvesen, Connor, Stewart, Simpson, and Playfair.

The method essentially consists in connecting the prime conductor of the Holtz machine, not with the electrometer directly, but with an insulated spherical ball placed at some distance from an equal spherical ball, the latter being connected with the electrometer. The woodcut represents, *in situ*, the apparatus which was used in the case of the gases. The receiver of the air-pump, which has a rod capable of moving air-tight, was attached to one of the conductors of the Holtz machine in such a manner that the conductor and the rod formed one conducting system. Projecting from the plate of the air-pump was a short metal rod, which formed one conductor with the metallic parts of the air-pump, and, by means of a wire, with the uninsulated conductor of the Holtz machine. Electrodes of various forms were made to screw on to the ends of the rods. Of the two insulated brass balls one, A, was fixed; the other, B, could be moved along the connecting board. The wire joining A to the collar of the receiver is insulated with gutta-percha. The electrometer in connection with B is one of Sir W. Thomson's divided ring reflecting electrometers.

When the potential of A is raised by driving the machine, the potential of B is also raised, and this goes on until a discharge takes place between the electrodes inside the receiver. Hence the maximum deflection of the spot of light from zero is an indication of the difference of potential of the two surfaces between which the spark passed immediately before the discharge. By breaking the contact between the conductors of the Holtz machine before beginning to turn the wheel, and, by turning slowly and uniformly, we were able to make the image of the



wire move up continuously, and to be at rest at the instant of discharge. After the discharge took place the image fell back to zero, or a point near zero. We always noted the position taken up by the image when the conductor of the machine was completely discharged.

The force resisting the deflection of the mirror is the action of two external magnets upon several small magnets fixed to the back of the mirror.[2]

One great merit of our method is the rapidity with which observations can be made. Three readings were in general taken for each entry. The mean of these is very probably free from any error due to accidental variations in the passage of the spark. An extensive series of observations have been printed in full in the *Transactions* of the Royal Society of Edinburgh. The following are the more important results:—

A spark was taken through air between plates at a constant distance, and the distance between the balls A and B varied. Let V denote the induced potential, and r the distance between the centres of A and B; then the experimental curve obtained satisfies the equation—

$$V = 6081 r^{-1} - 42{\cdot}26$$

for values of r greater than 24 centimetres; but for less values of r the function requires to be corrected by being multiplied by—

$${\cdot}524 + {\cdot}02r.$$

Sparks were taken through air at the atmospheric pressure between parallel metal disks of 4 inches diameter, for distances up to 1·2 centimetres. The function for V, the difference of potential in terms of s, the length of the spark is—

$$V = 66{\cdot}91 \sqrt{\{s^2 + {\cdot}205 s\}},$$

[1] Abstract by the author of thesis for D.Sc. and other papers printed in the recently issued part of the *Transactions* of the Royal Society of Edinburgh. By Alexander Macfarlane, M.A., D.Sc.

[2] Our results were reduced to absolute measure by means of the absolute electrometer represented on the table.

the equation of a hyperbola whose semi-transverse axis is ·1025 centimetres, and semi-conjugate axis 6·8623 C.G.S. units. From the above equation we infer that—

$$K = 66{\cdot}94\sqrt{\left\{1 + {\cdot}205\frac{1}{s}\right\}}$$

where K denotes the electrostatic force; from which it is evident that as s becomes smaller K becomes greater. A similar curve was obtained when hydrogen was substituted for air.

When the disks were heated before taking the sparks, the curve obtained satisfies the equation—

$$V = 87{\cdot}04s - 19{\cdot}56s^2,$$

a parabola, from which we deduce—

$$K = 87{\cdot}04 - 19{\cdot}56s.$$

It was found that when the capacity of the charged conductor was changed, the difference of potential required to produce a spark remained constant.

When the discharge was continued so as to keep the spot of light at a fixed deflection, the reading was always less than for the corresponding single discharge, but the curves were similar.

Readings were taken of the difference of potential required to produce a ·5 centimetre spark through air at different pressures from the atmospheric to 20 mm. They give—

$$V = {\cdot}0358\sqrt{(p^2 + 203p)}$$

where p denotes the pressure in millimetres of mercury.

The electric strengths of several gases were determined by comparing the differences of potential required to pass a ·5 centimetre spark through the gas at the atmospheric pressure.

Dielectric.	Electric Strength.		
	Macfarlane.	De la Rue and Müller.	Faraday.
Air	1	1	1
Carbonic Acid ...	·95	1·06	·91
Oxygen	·93	1	·71
Hydrogen... ...	·63	·54	·53
Coal Gas	·93	—	·71

"Electric strength" is the term used by Prof. Clerk-Maxwell to denote the physical constant in question. I have added, for the sake of comparison, values deduced from the results of De la Rue and Müller and of Faraday, but the ratios given do not strictly give the relative electric strength, but the ratio of the lengths of spark when the difference of potential is kept constant.

The difference of potential required to produce a spark between two spherical balls is approximately proportional to the square root of the length of the spark. This we have verified up to 15 cm.

On proceeding to investigate the discharge through insulating liquids, we first took up oil of turpentine. The liquid was placed in a glass jar of 7 inches diameter and 5 inches height. A screw passing through the bottom of the jar served to fix the lower electrode, and also to afford conducting connection with the earth. We observed four modes of discharge: by means of threads of solid particles, by motion of the liquid, by a disruptive discharge, and by motion of gas bubbles. When a chain was formed the index of the electrometer behaved as if a current were passing. The discharge, when sufficiently great, broke the thread and turned into a spark. The liquid was more easily set in motion when its surface was not much higher than the upper plate. The bubbles of gas appeared to be formed by the passing of the spark. They were always attracted to the negative electrode. When the electrification was neutralised they of course adhered to the under surface of the upper disk; when the disk was electrified negatively they still adhered; when positively they were repelled so as to remain suspended in the liquid or to adhere to the lower electrode, according to the greater or less distance between the electrodes. At a diminished pressure the bubbles produced at the upper surface were observed to effect the discharge by carrying the electricity with them to the negative electrode. The fact that it is possible to cause a shower of electrified bubbles to descend and produce a flash and sound on impinging on the lower surface appears to throw some light upon the nature of lightning balls.

Similar phenomena were observed in paraffin oil, excepting that the gas bubbles produced were generally attracted to the positive surface.

We observed the differences of potential required to pass a spark through paraffin oil and oil of turpentine between plates for distances up to ·5 cm. It was impossible to observe for greater distances, as our insulated wire allowed the charge to escape. For paraffin oil,

$$V = 750s - 15;$$

therefore, $K = 750.$

The above has not been reduced to absolute measure. Thus K is constant in the case of the liquids, but variable in the case of the gases.

Electric Strength of Liquid Dielectrics

Air	1
Paraffin Oil (kind used for burning)	4
Oil of Turpentine	3·7

Sparks were taken between two platinum wires placed at right angles to one another. When one of the wires was heated by a voltaic current the electrometer deflection was diminished by about one-fourth of its amount.

We have also investigated the effect upon the electric spark of heating the air round the disks, the pressure being kept constant. The deflections of the electrometer for a constant spark for temperatures from 20° C. to 280° C. indicate a curve which slopes down gradually as the temperature is increased, while the deflections during cooling give a curve which is somewhat lower at the lower temperatures.

These experiments were made in Prof. Tait's laboratory, to whom we are indebted, not only for the use of apparatus, but also for ever ready advice.

ON THE MINUTE MEASUREMENTS OF MODERN SCIENCE.

By Alfred M. Mayer.

Article XVIII.

On the Application of Rotating Mirrors to the Measurements of Minute Lengths, Angles, and Times.

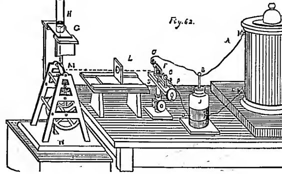
THE EXPERIMENTS OF FEDDERSEN, HENRY, ROOD, AND MAYER ON THE NATURE AND DURATION OF THE ELECTRIC DISCHARGE.

If we except a remarkable discovery made by Joseph Henry in 1841, nearly a quarter of a century elapsed before anything of value was added to the information which Wheatstone had given us about the nature of the electric discharge.

In the year 1858, Professor Feddersen, of Leipsic, began a series of elaborate and refined experiments on the electric spark. The peculiarity of his method consisted in replacing the plane mirror, which Wheatstone had used, by a concave mirror (of one-half meter radius), which gave an image of the spark by reflecting its rays on to a piece of finely ground glass. In this image the observer could see the structure of the spark. This is an improvement of prime importance, and the want of it prevented Wheatstone from really seeing what his mirror otherwise would have revealed to him. In fact, as we shall soon see, the spark, as observed by Wheatstone, was so brilliant and minute that its more feebly luminous and colored parts could not be seen. As this brilliant part of the spark has a very minute duration—less than the millionth of a second—it followed that Wheatstone decided that the whole of the electric spark has a duration less than the above fraction of a second.

Feddersen studied the images of the electric spark given by the concave mirror when it was stationary, and then when it was revolving 100 times per second. He made both drawings and photographs of these appearances. Feddersen divides electric discharges into three kinds:

1st. *The continuous discharge.* The rotating concave mirror gives an image of this, composed of a brilliant narrow line joining the electrodes, and parallel to the axis of rotation of the mirror. At the ends of this line, and at right angles to it, appear two faintly luminous bands. The noise given by this kind of discharge is a sharp crack.



PROF. ROOD'S APPARATUS.

2d. *The intermittent discharge*, formed of a series of luminous lines (parallel to the line joining the electrodes), and separated by dark spaces which become wider as the lines are further from the electrodes. This discharge makes a crackling or rustling noise, and appears to the naked eye as "the electric brush."

3d. *The oscillating discharge*, composed of a series of luminous brushes or cones, which start from two lines drawn at right angles to the ends of the line which joins the electrodes. These brushes curve around till they are parallel to these lines, and are alternate in their positions. Fig. 61 shows the appearance of this character of discharge, which was predicted by Henry in 1841, and first actually seen by Feddersen in 1862.

With his mirror running with a velocity of 100 revolutions per second, Feddersen saw the image of the spark of a discharging Leyden jar drawn out to the length of 20 to 30 millimeters. Using a larger jar, he observed that the spark was elongated to 20 millimeters more by the addition of a reddish tail formed of the gradually cooling metal volatilized from the electrodes. He found that an increase of "the striking distance" between the electrodes, as well as an increase of surface of the Leyden jar, gave the spark a longer existence. Thus, with a jar of 2·2 square feet of surface, and the electrodes 1½ millimeter apart, the spark's duration was 1-25,000th of a second; but on separating the electrodes till the spark was 3½ millimeters long the entire discharge lasted about 1-14,000th of a second. Feddersen also found that by increasing the resistance of the conductor leading from one coating to the other of the jar he greatly lengthened the time of the duration of the discharge. Thus, with a column of water of 9 millimeters in length, placed in the circuit, the duration of the discharge was 1-764th of a second; when a column of water 180 millimeters long, and of the same area of section, was interposed the duration lengthened to 1-54th of a second.

The most remarkable, however, of Feddersen's discoveries was that of the oscillatory character of the discharge of a Leyden jar, the discharge appearing to act like an elastic fluid, which alternately rebounded from the inside and outside coatings of the jar. Fig. 61 is a reproduction of an engraving contained in one of Feddersen's papers, and made from a photograph obtained from the image of the spark, thrown by the rotating concave mirror on to a sensitive plate. No one who examines this remarkable picture can fail to see the oscillatory character of this discharge. The spark was taken from a battery of 10 large Leyden jars with a conductor of high resistance connecting the inside and outside coatings. The electrodes were balls of iron, coated with varnish except at two points, between which flashed the spark. In this picture the positive electrode was at the right, the negative on the left. The spark is not only greatly elongated in a direction at right angles to the line joining the electrodes, but it is discontinuous and formed of curved brushes of light which appear alternately from the electrodes: first, a discharge takes place from the right hand electrode, then from the left, then from right, then from left, and so on. We also remark that the light which forms the brush coming from the negative electrode (and shown in the lowest part of the figure to the left) is streaked or ribbed, while that which next comes from the opposite or positive electrode is continuous and nebulous in its appearance. Then these appearances change places in the next act in the discharge, and the ribbed brush is now on the right and the nebulous one on the left, and so on.

I regard this photograph as one of the notable results of the modern art of experimenting. Here is a permanent record of the most transient of phenomena engraved by Nature herself, and giving the life history of intense physical actions whose whole existence is crowded into the duration of a hundred-thousandth of a second. Yet, in that short time, how has its reign; each circumstance of the transaction, from the generation of the spark till its final impress on the "sensitized" plate, follows in its allotted order and with its proper direction, duration, and intensity.

Speaking of the above experiments, those of Henry naturally recur for this remarkably talented experimenter saw with his mind's eye in 1841 what Feddersen, twenty years afterwards, succeeded in getting on his photographic plate. In a communication to the American Philosophical Society of Philadelphia, in 1841, Henry says: "The discharge, whatever may be its nature, is not correctly represented (employing the theory of Franklin), by the single transfer of an imponderable fluid from one side of a jar to the other; the phenomena require us to admit the existence of a principal discharge in one direction, and then several reflex actions backward and forward, each more feeble than the preceding, until the equilibrium is obtained. All the facts are shown to be in accordance with this hypothesis, and a ready explanation is afforded by it of a number of phenomena which are to be found in the older works on electricity, but which have, until this time, remained unexplained."

Henry was led to the above conception of the nature of the discharge of a Leyden jar by the observation of the magnetizing action of the discharge of the jar on needles, which were placed in a glass tube, around which a conducting wire was wound like a helix. Now when a needle, placed as above, has an electric discharge sent around it, it is magnetized, and the direction of its magnetism, that is, which of its ends will be N. or S. polarity, depends on the direction of the electric flash through the enveloping helix. But, to Henry's surprise, he found that the same end of the needle was sometimes of north and at others of south polarity, till, after many hundred experiments, he found that there was a connection existing between the direction of the polarity and the amount of charge the jar had, and on the distance over which its spark passed. Then it occurred to Henry that these phenomena could only be explained by the supposition that there were several flows, or oscillations, of the electric fluid, first from one coating to the other of the jar, then back again, and so on, and that the number of these alternate oscillations decreased with the striking distance, and increased with the surface of the jar. Thus the final magnetic condition of the needle depended on the direction and intensity of the last flash of electricity which encircled it. After Henry had promised all this he soon had such mastery over the phenomena that he could at will give to the end of a needle either polarity he wished.

Researches of Prof. O. N. Rood on the nature and duration of the discharge of a Leyden jar connected with an induction coil.—It must have been noticed that Feddersen gives for the duration of the discharge the length of time during which the whole electric explosion lasts; but this explosion is of a complex nature, and the separate acts which compose it now require our attention. The thorough study of the composite nature of the discharge (at least of one form of it) was the subject of a series of skillful researches made in 1869, 1871, 1873, and 1875, by Professor Rood, of Columbia College, New York, of which we will now give an account.

Feddersen's experiments were made on the spark of the Leyden jar kept charged with electricity from a frictional electrical machine. Rood's researches are on the nature and duration of the electric discharge of a Leyden jar which was charged and discharged while in the circuit of the secondary wire of an induction coil. The circumstances of the charging and discharging of a jar placed as in Rood's experiments, are quite different from those which had place in Feddersen's, for, while in Feddersen's the two coatings of the jar were always insulated, in Rood's these coatings were always in metallic con[illegible] through the secondary coil of the inductorium, both [illegible] charging and discharging of the jar—"a circ[illegible] as Rood remarks, "which alone might be supposed to modify the duration of the discharge and its nature; besides this, it is known that the electricity from the coil continues to flow for a considerable fraction of a second along the terminal wires into the jar, which fact renders it questionable whether the duration of the discharge of the jar itself may not be proportionately lengthened. Hence it is evident that it would not be safe to conclude, without experiment, that the results obtained by Feddersen with jars charged with ordinary frictional electricity were applicable to those connected with an induction coil."

Professor Rood in his experiment worked, like Feddersen, on the image of the spark formed on a piece of glass having either a finely ground or a polished surface. He, however, replaced Feddersen's concave rotating mirror with a small plane mirror and an achromatic lens; the latter forming an image of the spark on the plate of glass placed directly over the rotating mirror.

Fig. 62 shows the arrangement of apparatus in Rood's experiments. The jar, J, has its inside and outside coatings in the circuit of the secondary coil of the inductorium through the wires leading from A to B, and from E to D. These wires then proceed from B to C, and from D to P. The discharge of the jar takes place between the metallic balls, or pointed wires, on the spark discharger, S. One of these balls is shown on the standard at O. The two standards, carrying the balls or points, can be placed at determinate distances apart by means of a micrometer screw which moves them. The head of this micrometer screw is shown at R.

The rays of light from the spark pass through the achromatic lens, L (of 9 inches focal length), which forms an image of the spark on the ground or plane glass at G, after their rays have been previously reflected from the stationary or revolving mirror at M. The mirror generally used was about one half inch square, and was formed of two silvered mirrors placed back to back. Thus two reflections were obtained from the mirror for one revolution. The image of the spark on G was examined by a microscope, H, which magnified about five times.

The mirror, M, was rotated by the wheel-work, W. Driven by a weight of 30 lb., the mirror could be brought up to a speed of 340 rotations in a second. To measure the rate of its rotation the cylinder on the lowest wheel of the train wound up a fillet of paper, on which dots were made by a Morse register, through which a current was sent by a pendulum at each second. The number of rotations made in a second by the mirror was readily computed from the record thus made on the fillet.

Two Leyden jars were used in Professor Rood's experiments. The larger of these had a coating of 144 square inches of foil, the smaller had only 12 square inches of surface. The discharge of the larger jar differed from the smaller both in its nature and in its duration.

Professor Rood first began a careful study of the structure which the spark presented when its image was formed by reflection from the stationary mirror.

Placing the larger jar in the circuit and sending its sparks between pointed brass wires one millimeter apart, the image of the spark on the glass surface at G appeared as in Fig. 63 a; "a central white portion surrounded by a yellowish envelope, which in the figure* is shown by the coarse shading; the second envelope, more densely shaded, being green and much inferior in brightness. With a striking distance of ten millimeters, the green envelope was produced only in the neighborhood of the electrodes, as shown at B of Fig. 63. In both cases a number of minute jets of white light were seen to issue from the electrodes; these are only partially shown in the figures. The green color was due to the heated particles of metal, and the bright points of light to successive discharges, as will be shown further on."

With fine platinum wires for electrodes the appearance was the same as with the pointed wires, except that the green tint was replaced by a gray, or violet-gray hue.

* This and the remaining figures describing Professor Rood's work I owe to the kindness of Professor Dana, editor of the *American Journal of Science*.

72

actual duration of the discharge, another effort was made. A second lampblack plate was prepared, in which the breadth of the image of a line, black or white, on the observing plate, was 1-600th of an inch. These lines were viewed with the terrestrial eye-piece of a small telescope; it enlarged them ten diameters and care was taken with all the adjustments so that a good clean image should be produced. Platinum wires of 1-86th of an inch in diameter were used, with a striking distance of five millimeters. By gradually increasing the driving weight it was proved successively that the duration was less than eighty, sixty-eight, fifty-nine,

Fig. 68.

fifty-five billionths of a second; and finally, the lines, after growing fainter and fainter, entirely disappeared, giving as the result a duration of forty-eight billionths of a second. In a large number of observations I could detect no discharge lasting during a smaller interval, though the apparatus was now fully capable of making evident much smaller periods of time.

"When the striking distance was reduced to one millimeter, the duration was shorter; in the case of 5-6ths of the sparks, the duration was slightly greater than forty-one billionths of a second, the remaining 1-6th being slightly less than this figure.

"With a striking distance of three millimeters, the duration was between forty-one and forty-eight billionths; and when the striking distance was increased to ten millimeters, it was between forty-eight and fifty-five billionths of a second.

"It has thus been shown that the duration of the first act of the electric discharge (of this small jar) is in certain cases only forty billionths of a second, an interval of time just sufficient for a ray of light to travel over forty feet."

Professor Rood adds: "With another ruled plate I found it practicable to measure intervals as small as twenty-eight billionths of a second; and the mere act of increasing the focal length of the lens, L, would admit of the experi-

Fig. 69.

menter reaching a quantity as small as ten billionths—probably without much difficulty—though it would be necessary to pay more attention to the correction of the optical part of the apparatus, and the observations would naturally consume threefold as much time."

Professor Rood gives, in his paper, the accompanying curve, Fig. 65, by which he shows the duration of the whole discharge and the relative brightness of its various parts. The time during which the discharge lasts is represented by the length of the horizontal line, A C, and the relative degrees of brightness of the discharge at points of time, measured on the horizontal line, A C, are represented by the perpendicular distances of the curve (the unbroken line) from these points on the horizontal line. This curve shows that there is no break in the discharge; it is a continuous act. The steep peak, A B, stands for "the first and most brilliant act of the discharge;" though with the larger jar, of 114 square inches, it is neither so steep, as in the present case, nor so solitary, being followed by a series of minor elevations, while with the small jar the effective luminosity of the discharge is almost wholly concentrated in it; the far greater brilliancy of the light at the beginning of the discharge practically separates it from what follows, and makes

used, the cross and rings around the axis of crystals can be observed with all their peculiarities, and errors in the azimuth of the analyzing prism noticed. There seems also to be evidence that this minute interval of time is sufficient for the production of various subjective optical phenomena: for example, for the recognition of Loewe's rings (using cobalt glass); also, the radiating structure of the crystalline lens can be detected when the light is suitably presented to the eye."

Hence, it is plain that forty billionths of a second is quite

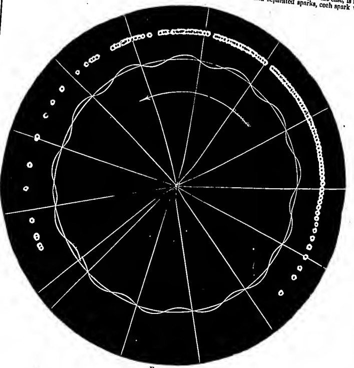


Fig. 71.

sufficient for the production on the retina of a strong and distinct impression; and as the obliteration of the micrometric lines in the experiment referred to could only take place from the circumstance that the retina retains and combines a whole series of impressions, whose joint duration is forty billionths of a second, it follows that a much smaller interval of time will suffice for vision. If we limit the number of views of the lines presented to the eye in a single case to ten, it would result that four billionths of a second is sufficient for human vision, though the probability is that a far shorter time would answer as well, or nearly as well. All of which is not so wonderful, if we accept the

fessor Rood used two instruments in his study of these multiple discharges, viz., the revolving mirror already described, and a rotating disk with a slit cut out of it in the direction of one of its radii. If we look at a sheet of white paper through this slit while the disk is rotating, and the paper is illuminated by one instantaneous flash, we evidently will see the slit on the disk appear as a white radial band. If, however, the discharge, as usually is the case, is formed of several distinct and separated sparks, each spark will in order illuminate the slit, and we will see a white radial band on the disk for each separate spark; provided, however, that these sparks do not follow one another so rapidly that the disk has not time enough to carry the slit far enough to prevent the bright radial bands from blending into one broad band.

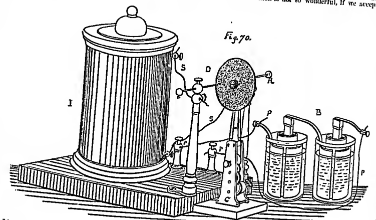
To facilitate the observations on these complex phenomena Professor Rood devised what he called a micrometer-disk, formed of two disks superposed. Each disk had a radial slit cut in it, and one of these disks revolved on the other so that the slits could be placed at various angular distances apart. Fig. 66 shows the disks of blackened cardboard with the two slits. On viewing through the revolving disk the white paper surface, illuminated by the electric flash, the slits in the disk appeared as in Fig. 67. By revolving the inner disk on the larger one the two fan-like images of the multiple slits could be brought together so that the end of one just touched the beginning of the other, and thus the angular breadth of the set of multiple slits was readily measured. This measure, with the knowledge of the velocity of rotation of the disk, gives us the data for computing the total duration of these discharges.

Flashing the discharge of his coil between brass balls one millimeter apart, and viewing the discharge in the rotating mirror, the appearance of the flash was as in Fig. 68, showing that sometimes the discharge was formed of three separate sparks, and sometimes of four. The duration of the whole discharge was about 1-165th of a second, the interval separating the sparks being about 1-500th of a second. With a striking distance of two millimeters he observed only one spark.

With platinum points as electrodes, and separated 1, 2, 3, 4, and 5 millimeters, the number of sparks observed at these respective distances of the electrodes was 4, 3, 2, 1 and 1, showing that an increase in the striking distance of the discharge diminishes the number of its component sparks. Placing in the circuit of the induction coil the small Leyden jar of eleven square inches of surface, and sending the discharge between brass balls separated by one millimeter, the character of the discharge, as shown by the revolving mirror and of the rotating disk, was more complex. Fig. 68 shows the appearance it presented on the revolving mirror. Here we see that the act of discharge was formed of a bright spark followed by a violet discharge, extending from C to A, and the latter followed by four sparks, extending from A to B. The total duration of these discharges was 1-50th of a second. The violet portion, C A, lasted for 17-1000th of a second, and the four sparks, between A and B, lasted the 9-1000th of a second. Other forms were sometimes present, like that in Fig. 69, consisting of a faint violet streak terminated at each end by a spark, the whole duration being about 1-35th of a second.

On increasing the striking distance between the balls to 2, 3, 4, 5, 6, 7, 9, and 10 millimeters, the total number of sparks forming the discharge for these striking distances was respectively 5, 3, 4, 3, 3, 3, 2, and 1 spark.

Professor Mayer's Experiments on the Electric Discharge of the Induction Coil.—Professor Rood's mode of experimenting is not competent to unravel the tangle of sparks composing a flash from an induction coil, for the number of separate electric actions forming the discharge are far too many over



MAYER'S APPARATUS FOR ANALYZING THE ELECTRIC DISCHARGE.

it a first distinct act, whose duration, as we have just seen, Rood measured, and showed that its existence lasts for only forty billionths of a second.

After the success of his remarkable experiments, in which Rood showed that the flash of light from the small jar lasted for only forty billionths of a second, he made some very curious reflections on the very short time necessary for distinct vision. We will give his own words: "I obtained and measured sparks the duration of whose main constituent was only forty billionths of a second. With their light distinct vision is possible; thus, for example, the letters on a printed page are plainly to be seen; also, if a polariscope be

doctrines of the undulatory theory of light; for according to it, in four billionths of a second, nearly two and a half millions of the undulations of light reach and act on the eye.

On the multiple character of the discharge of the induction coil.—In the course of his experiments on the electric discharge Professor Rood observed that the explosive act of the induction coil was not concentrated into a single spark, but was formed of several distinct flashes, which, it is true, to the naked eye appear as a single flash; but on examination in the revolving mirror this apparent single spark appears as formed of several distinctly separated sparks. LA PHILOSOPHIE DE L'ÉLECTRICITÉ

—

Les unités électriques et le peseur

On nous demande de toutes parts en quoi consiste la comparaison des différentes unités électriques, sujet que l'on peut dire entièrement neuf en France, car les traités de physique élémentaire n'en parlent que d'une façon tout à fait superficielle. Mais avant de répondre à nos correspondants, nous devons commencer par bien définir la portée philosophique du problème dont ils nous demandent de nous occuper, afin de ne donner prise à aucune des ambiguïtés dont se servent certains physiciens pour jeter une confusion regrettable dans les notions les plus simples, les plus élémentaires et les plus claires.

Qu'il nous soit permis de prendre un exemple :

Les astronomes entassent chiffres sur chiffres et raisonnements sur hypothèses sans prendre garde qu'ils ont omis d'adopter une *unité spéciale*, oubli qui paraîtra singulier de la part de savants prétendant que leur science doit servir de modèle à toutes les autres, suivant l'orgueilleuse expression de M. Auguste Comte.

L'auteur de la *Philosophie positive* ne paraît pas avoir soupçonné même l'avantage qu'il y aurait à faire pour l'astronomie ce que l'on fait pour les besoins vulgaires du commerce et de l'industrie. Il n'a pas vu que depuis l'établissement du système métrique, les simples épiciers possédaient, à cet égard, un immense avantage sur les élèves les plus dociles de Laplace et de Newton.

Nous allons essayer de réparer cette omission, non point pour obéir au futile plaisir de les prendre en flagrant délit, mais afin de leur faire comprendre notre pensée, s'ils daignent nous lire.

Quelle doit être l'unité de masse astronomique ? Est-ce la masse du soleil, ou celle de la terre, comme on le fait chaque année dans les tableaux que publie la *Connaissance du Temps?*

En aucune façon, il faut que ce soit la quantité de matière qui, concentrée en un point unique, donne à une masse pondérable quelconque, se mouvant dans le vide, l'unité de vitesse après avoir agi pendant l'unité de temps, ladite masse attirée ayant été placée à l'unité de distance du centre attirant.

Si les astronomes veulent obéir à la logique dont les électriciens reconnaissent depuis longtemps la nécessité, ils ne peuvent agir autrement.

C'est, en effet, à ces différentes conditions que les physiciens ont reconnu la nécessité de se soumettre pour comparer les différentes forces dont ils ont à s'occuper.

Rien n'est plus logique, plus normal, plus conforme au génie de la mécanique, plus impérieusement exigé par la logique à laquelle les astronomes n'ont pas le droit de se soustraire.

Mais n'a pas une unité de matière, qui veut.

Pour avoir une unité de matière, il faut, nous venons de le montrer, avoir une unité de distance, une unité de temps, une unité de vitesse.

Quelle est l'unité de distance pour les astronomes? Les uns prennent l'année de lumière, ce qui est beaucoup, d'autres la lieue, ce qui est très-peu. Les uns prennent tantôt l'une, tantôt l'autre, mais aucun n'a senti le besoin d'une règle uniforme.

Quelle est l'unité de temps? A ce propos, même incertitude et cacophonie plus grande encore s'il est possible.

Les uns prennent la seconde sidérale, les autres le jour solaire moyen; quelques autres, l'année solaire moyenne. Les uns prennent indifféremment, avec une désinvolture tout académique, plusieurs unités qui n'ont point de rapport commensurable.

Quant à l'unité de vitesse, certains astronomes prendront le mètre, d'autres la lieue.

Nous ne nous chargerons point de les mettre d'accord. Nous dirons seulement qu'un certain nombre d'astronomes anglais, prenant le pied pour unité de longueur et la seconde pour unité de temps, ont été amenés à prendre comme unité de

76

ON THE SPECIFIC INDUCTIVE CAPACITIES OF CERTAIN DIELECTRICS.

By J. E. H. GORDON, B.A. Camb.*

79

As it would be impossible within the limits of an abstract to give any intelligible account of the new method of experiment (due to Professor Maxwell) which has been employed, I will merely give the table of results, reserving all discussion and explanation until the publication of my paper in full.

I may, however, state that the method is a zero method, that the electrified metal plates never touch the dielectrics, and that the electrification, which is produced by an induction coil, has an electromotive force equal to that of about 2,050 chloride of silver cells, and is reversed some 12,000 times per second.

RESULTS.

Extra dense flint	1·7474	1·6757	
Light flint	1·7343	1·5113	
Hard crown	1·7629	1·5920	
Plate glass	1·8009	1·543	
Paraffin	1·4119	1·422	Rays of infinite wave length.
Sulphur	1·6060	2·115	
Bisulphide of carbon	1·3456	1·6114	

[These results are, we understand, a correction of those given before by Mr. Gordon. See TELEGRAPHIC JOURNAL for July 15, 1878.—ED. T. J.]

* Messrs. Gibson and Barclay, "Phil. Trans," 1871, using a method entirely different from mine, obtained K=1·977 for paraffin. Correcting for a slight difference of density; I find that if they had used my paraffin their result would have been 1·9833.

† I am not quite certain of the accuracy of this result.

77

absorption spectra only indicate the component parts of a compound so long as the colour of a given substance is characteristic of its chemical composition.

WE notice an interesting discussion which arose at the last meeting of the Russian Society of Hygiene. M. Malarevsky, pointing out the yearly increasing myopy of scholars, proposed to print books with white letters on a black field, and proved the superiority of this system by experiments he has made with fifty scholars, as well as by experiments on the facility of discernment of black drawings on a white field and of white drawings on a black field, these last always being better seen from a greater distance than the former.

WE have received a very full Catalogue of Official Reports upon Geological Surveys of the United States and Territories and of British North America, by Mr. F. Prime, assistant-geologist of Pennsylvania. It seems to be an enlarged continuation of the Catalogue by Prof. O. C. Marsh, published in the *American Journal* for 1867. The present list covers 50 pp.

AT the last session of the U.S. Congress an appropriation of 250,000 dols. was made for the construction of a fire-proof building for the reception of such collections belonging to the National Museum as cannot be at present accommodated in the Smithsonian Building; and as the plans have already been prepared, it is understood that the work will be begun without delay. The design contemplates a building 301 feet square, with certain projecting corners, the whole covering a space of about 97,000 square feet. Although not quite equal to the area of the Government Building at the Centennial, it is capable of containing a much larger mass of material. The general plan is that of a pavilion, of one story, with brick walls and iron roof, the floor to be of concrete. The corner buildings or projections constitute offices connected with the administration of the Museum, to include a library room, a small lecture-room, and others. It is expected that the entire edifice will be completed and ready for occupation by April 1, 1880.

THE whale whose bones have been so long exposed in the court-yard of the Jardin des Plantes at Paris, is to be demolished in compliance with a report from M. Quatrefages, who shows that the original number of vertebræ has been enlarged, and a series of important alterations have been successively made.

THE publishing office of *Science News*, hitherto published at Salem, Mass., will shortly be removed to New York.

MANY of our readers might like to know of Dr. Karl Möbius' address on March 5 last, on his assumption of the rectorship of the University of Kiel. Its subject is the passage from Goethe—"Leben ist die schönste Erfindung der Natur, und der Tod ist ihr Kunstgriff viel Leben zu haben."

THE Second Annual Report of the Board of Trustees of the Western Pennsylvania Institution for the Instruction of the Deaf and Dumb is one of great interest, and we are sure would be perused with pleasure and profit by all who are interested in the important subject. The Institution seems to be conducted on thoroughly scientific principles, and its success seems very marked. The Report is published by Stevenson, Foster, and Co., Pittsburgh.

WE have received a cheap edition of "The Caves of South Devon and their Teachings," by Mr. J. E. Howard, F.R.S., in which he endeavours to combat the long chronology assigned to the human race by Mr. Pengelly and others. Hardwicke and Bogue are the publishers.

THE *North British Daily Mail* of March 29 contains reports of recent meetings of the Geological and Natural History Societies of Glasgow. In the former Mr. Young gave a descriptive notice of an interesting specimen of *Elephas primigenius* discovered about four years ago when sinking a pit-shaft on Mainhill Farm, near Baillieston, east of Glasgow. In the latter Mr. Harvie-Brown read a paper on the Mammalia of the Outer Hebrides.

"NEW Views in Astronomy, Illustrated by Working Models and Diagrams, and Demonstrated by Inductive Philosophy," is the title of a quarto pamphlet by Mr. John Harris, published by Wertheimer, Lea, and Co., of Finsbury Circus.

THE additions to the Zoological Society's Gardens during the past week include a Yak (*Bison grunniens*) from Bhootan, presented by the Hon. Ashley Eden, K.C.S.I.; a Japanese Goat Antelope (*Capricornis crispus*) from Japan, presented by Mr. H. Pryer, C.M.Z.S.; a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. J. Roberts; a Grivet Monkey (*Cercopithecus griseo-viridis*) from West Africa, presented by Mr. W. B. Greenfield; a Common Seal (*Phoca vitulina*), British Isles, presented by Capt. Chas. Rawle; a Red-throated Diver (*Colymbus septentrionalis*), British Isles, presented by Mr. J. S. Thompson; a Masked Parrakeet (*Pyrrhulopsis personata*) from Fiji, an Entellus Monkey (*Semnopithecus entellus*), from India, deposited.

THE RESULTS OF RECENT RESEARCHES IN ANIMAL ELECTRICITY[1]

I.—INTRODUCTORY OBSERVATIONS

The State of the Subject Ten Years Ago

UNTIL the year 1867 certain theoretical conceptions based upon the classical investigations of du Bois-Reymond prevailed in the whole department of animal electricity. It may indeed be said that du Bois-Reymond created this branch of modern physiology, for it was he who first struck out the modern method of research and gave the lead to recent investigation. To his individual labours we owe not only the establishment and the orderly arrangement of many facts which had been left ill-defined by his predecessors, but also the actual discovery of a still greater number of fundamental value. These fundamental facts, briefly summarised, were the following:—

1. Muscular fibres and nerve-fibres when cut across exhibit a current directed within them from the transverse to the longitudinal surface, the electromotive force of which may equal one-twelfth of a Daniell's cell.

2. The negative potential of the transverse section also belongs, though in a less degree, to the natural terminations of the fibres of muscle ("natural transverse section"); but in this case it may be wanting, or even be changed to a positive potential. This diminution, absence, or reversal, of the common condition, to which the term "parelectronomic state" is applied, would seem to be favoured by the continued action of cold.

3. If a certain portion of a nerve-fibre be traversed by a galvanic current, the remaining portions, or the extra-polar regions, become the seat of an electromotive force which has the same direction as the traversing current, and which is strongest in the vicinity of the poles (electrotonus). This influence extends only so far as the structural integrity of the fibre is complete.

4. Muscles and nerves with artificial transverse sections exhibit during the period of stimulation a diminution ("negative variation") of their proper current. In uncut muscle the negative value of the diminution or variation becomes algebraically added to whatever current may be already present in the natural termination of the muscle.

Upon these facts du Bois-Reymond had based the following theory:—

1. Muscle- and nerve-fibres contain electromotive molecules suspended in an indifferent conductor, which present positive surfaces to the longitudinal surface or section, and negative surfaces to the transverse surface or section.

2. At the natural terminations of the muscular fibres are arranged particles of a peculiar kind, the presence of which is

[1] A lecture delivered on February 2, 1878, before the Medical Society of Zurich, by Dr. L. Hermann, Professor of Physiology in the University of Zurich, and published in the "Vierteljahrschrift d. naturf. Ges. in Zurich," 1878. All the papers referred to in this lecture which have no author's name attached are papers of the author himself.

78

79

the forces of the local currents are, on account of the usual oblique application of the muscular fibres to their tendons, generally summed into currents of inclination.

III.—Electrotonus

Considerations opposed to the Molecular Theory of Electronus

The explanation adduced in the Introductory Remarks, in order to elucidate the electrotonic condition of nerves has many theoretical difficulties which cannot be here entered upon. The theory appears, however, to be amenable to an experimental proof. If, namely, the molecules of the portion of a nerve traversed by a current arrange themselves in the direction of the current, the electromotive force of the current should receive a very appreciable increase; or, in other words, the current should become very much greater when it passes through a piece of living nerve than when it traverses a dead piece of similar dimensions. On trying this experiment, however, I find no such difference; or the differences found are far from agreeing with the molecular theory.[1]

Electrotonic Phenomena observed in Conductors with Polarisable Cores

An experiment of Matteucci's[2] gave the clue to an explanation of electrotonic phenomena. He found that a metallic wire which is surrounded by a moist envelope exhibits currents possessing the characters of the electrotonic currents of nerves, whenever a galvanic current is passed, at any point, through the moist envelope. Matteucci discovered, in addition, that the currents cease when the wire is of amalgamated zinc and the envelope is moistened by a saturated solution of zinc sulphate. Hence it follows that the phenomenon depends upon a polarisation between the core and the fluid.

I examined the phenomenon more closely,[3] passing metallic wires through a glass tube filled with fluid and possessing lateral processes for the conduction of currents, and my experiments confirm the fact that electrotonic currents only occur when a polarisable core is present. Further, it was seen that the currents only extended so far as both core and envelope possessed unbroken continuity, whereas continuous contact of the two was not necessary. Lastly, I determined the laws regulating the time of development of these currents, their duration, their cessation on opening, their dependence upon the distance, and the length of the portion of core traversed by the polarising current, their combination and superposition, &c. All the phenomena may be grouped without difficulty under a simple theory.

As the current *a E k* (Fig. 4) applied to the envelope endeavours to reach the core K K, it splits up, if no polarisation be present,

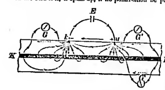

Fig. 4.

in such a manner that only the conducting threads in the immediate neighbourhood of the electrodes are able to catch an appreciable branch of the current. If on the other hand polarisation occurs at the surface of the core, this surface opposes a considerable and evenly distributed resistance; and, as in relation to it, the resistance offered by the length of the conducting wires is small, the current, under the influence of polarisation, extends much further along the conductor than when no polarisation takes place. If a galvanometer circuit is arranged as shown in the diagram (at G, G', or G") it receives an offset from the main current as if there existed in the region examined an electromotive force of like direction with that of the polarising current.

[2] Matteucci, *Comptes Rendus*, lvi. p. 760, 1863; lxv. pp. 151, 194, 884, 1867; lxvi. p. 580, 1868.
[3] "Arch. f. d. ges. Physiol.," v. p. 264, 1871; vi. p. 312, 1872; vii. p. 302, 1873.

This polarisational extension of the current only continues where both core and sheath are uninterrupted.

The abducted currents are at the same time, on mathematical grounds, a measure of the degree of polarisation at the points touched; and thus afford a means of tracing the extent of polarisation along the core. The curve representing the polarisational values at various points of the core—in general an exponential curve—has at the positive pole a positive maximum and a negative at the negative pole. In the region traversed by

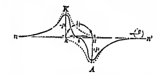

Fig. 5.

the current the curve cuts the axis at the so-called "indifferent point" (Fig. 5, *i*); and in the extra-polar regions it approaches the axes on both sides asymptotically. The curve is represented in Fig. 5, where, as a matter of subsequent convenience, the ordinates of positive polarisation are taken below the axis instead of above.

Internal Transverse Polarisation of Muscles and Nerves

In the year 1871 I discovered that the resistance offered by muscles and nerves to the passage of a current across their fibres was from five to nine times greater than the resistance offered by a current passing in direction of the fibres.[1] In the case of muscle this difference disappears almost entirely when rigor sets in; whilst in dead nerves it certainly persists, though reduced to one half. Further investigation of these facts disclosed their dependence upon a specific internal polarisability, which, in the case of muscle, is entirely associated with the living condition, and, in the case of nerve, in great part so associated. This fitness for polarisation by transversely-directed currents can only be due to a stratification of heterogeneous conductors across the tissue, which is wanting in its longitudinal axis. And since it is common to muscles and nerves, the stratification on which it depends must be sought in the typical structure which is common to the two organs, viz., the tubular nature of the fibres. We may assume, therefore, that polarisation takes place between the peculiar, active, substance of muscle- and nerve-fibres and the indifferent tissue ensheathing it.

Explanation of the Electrotonus of Nerves

As, accordingly, there exist in nerve-fibres all the essential conditions of the electrotonic extension of currents in conductors with polarisable nuclei, it may be assumed that the electrotonus of nerves is fully explained.[2] It is true that the core-substance of nerves is no better a conductor of electricity than the sheath-substance, while in the sheathed wire of Matteucci's experiment the core was of metal. But theory teaches that the electrotonic extension occurs even when the conducting powers of sheath and core are equal, if only polarisation takes place between the two.

This explanation of electrotonus, as I have shown in detail, completely covers all the phenomena. Especially does it account for the facts that the electrotonic state requires no appreciable time for its establishing;[3] and that it cannot extend past a ligatured spot. Whenever a nerve is crushed, the continuity of the core is broken, since, at the crushed spot, the core is killed and converted into indifferent tissue.

As muscle-fibres also possess polarisable cores, they must be endowed with electrotonic properties; nevertheless, neither du Bois-Reymond nor I at first succeeded in demonstrating them by galvanometric means; though, truly, just as little could their absence be distinctly affirmed. But theoretical considerations disclosed the reasons why muscle was less favourable to electrotonic phenomena than nerve;[4] and lately I have suc-

functional current. These forces were assumed to be located in the two extremities of the muscular fibres and to be directed each to the correspondent end of the fibre, on which account they would of necessity overlap. The descending functional current belonging to the lower end was supposed to arise more quickly and to disappear earlier than the ascending current of the upper end; and hence the appearance of phases. Inasmuch as injury to one of the ends of a muscle (or in other words, removal of the parelectronomic layer), according to Du Bois-Reymond, intensifies the functional current proper to that end, it is clear that, when the inferior extremity is injured, the lower (descending) functional current obscures the upper.[1]

My own explanation[2] is essentially different from du Bois-Reymond's. According to my views the muscle must exhibit a descending current when the excitatory wave is at the upper end of the muscle, and an ascending current when at the lower end. Hence it is not the first, but the second phase, which is proper to the lower end of the muscle. The former, as I have shown, pertains to the moment when the excitatory wave is in the neighbourhood of the upper electrode—a condition most advantageously secured, owing to the peculiar structure of the gastrocnemius, by placing the electrode so as to abduct a current from the mid point of the fibres rather than from their upper end.

According to this theory it is clear that the descending phase must precede the ascending: for every excitatory wave is started at the middle point of the muscular fibre where the nerve enters, and only reaches the ends of the fibres at a later period. If, however, the lower end of the fibre have suffered injury, the excitatory wave running towards the injured part will be powerless to cause a current, owing to the constant negative potential of the injured end, and hence the second, ascending phase comes to nothing.

The fitness of this explanation was placed beyond doubt by experiments on the phasic functional current of regularly-constructed muscles.[3] In such muscles there invariably appeared in each half first an atterminal and then an abterminal phase

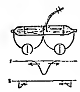

FIG. 6.

(Fig. 6). The atterminal phases in both halves (1 in Fig. 6) coincide in time, arising, as they both do, in the mid-point of the fibre at the starting of the excitatory wave; in other words, the middle point of the fibre becomes negative in comparison with either end.

In like manner the abterminal phases of both halves coincide (2 in Fig. 6), being produced by the arrival of the excitatory waves at the extremities of the fibre: in other words, either end of the fibre becomes negative in comparison with the mid-point.

In this manner the wave-like propagation of the excitatory condition in muscle was established for the case of muscle stimulated through nerves, and, at the same time, another proof was afforded that the force of the functional current does not exclusively reside in the ends of the fibres.

Furthermore, it was directly shown in these experiments that the excitatory-wave in excised muscles, while traversing the fibres, experiences a diminution; for the second, abterminal phase was invariably much weaker than the atterminal, as is indicated in Fig. 6 by the length of the arrows and the height of the representative curve, and it invariably further diminished in the course of an experiment.

The Functional Current in wholly Uninjured Muscle in Man

In the case of man the currents of normal resting muscle were secured from investigation by the obstacle of the skin. But Du Bois-Reymond found, during the violent voluntary contraction of the muscles of an arm or a leg, that the limb exhibited an ascending current. This he took to be the algebraical sum of the tetanic functional currents of all the muscles exerted, although such an explanation only became very probable by the exclusion of certain other experiments designed to elucidate the matter.[1] But the current could never be demonstrated under the most favourable conditions of abduction, viz., by the application of the galvanometer wires to individual groups of muscles.[2]

The question whether the diminution of the excitatory wave only occurs in excised muscles as a result of death changes, could, of course, only be settled by experiments on living human beings. And since the manifold disturbances inseparable from the method of experiment rendered the tetanic functional current almost useless for this investigation, I undertook to examine the *phasic* current in the muscles of the fore-arm.[3] I found that the same relationship held for the muscles of man as had before been shown to exist in the case of the frog. The first phase is an atterminal current in which the region of the nervous equator—about 10 cm. below the elbow—becomes negative in comparison with the two ends; the second phase is abterminal, *i.e.*, the ends of the muscles become negative in comparison with the equator (Fig. 7). But in the perfectly

FIG. 7.

normal muscles of man the second phase was *not* weaker than the first—a relation which was constant in the excised muscles of the frog. And hence we may conclude that in absolutely normal muscles the excitatory wave does not diminish in intensity. These experiments, which constitute the first regular examination of muscular action in living man, further taught approximately the rate of propagation of the excitatory wave in human muscles, viz., from 10 to 13 metres per second.

The Absence of the Functional Current when none of the above Conditions of Electrical Inequality exist in Muscle

If an uninjured, currentless muscle be thrown into the active condition by a stimulus affecting its whole mass at once, it never exhibits any functional current,[4] whether the stimulus be single or tetanic. The explanation of this is obvious. In such a totally excited muscle the whole substance passes at the same moment into the same degree of excitation; and, hence, is nowhere the opportunity given for the contact of excited with non-excited or imperfectly excited tissue.

If, on the other hand, the muscle possesses an artificial transverse section with the associated boundary current, then indeed a levelling or equalising functional current arises on total excitation and diminishes the current of injury.[5]

When muscles are tetanised through their nerves, functional currents only appear where the excitatory wave has not the same intensity throughout the tetanised mass. Hence in man, whose muscles when under absolutely normal conditions exhibit no diminution or decrement of wave, it is impossible to demonstrate a tetanic functional current. I have, indeed, when using very powerful and fatiguing stimulation, now and then succeeded in getting indications of such a decremental functional current, but from some cause or other, we cannot depend upon this experiment to lead to a constant result, perhaps for the reason that the conductivity of human muscles is but slightly hampered by fatigue, or possibly because the collateral effects of stimulation mar the experiment.[6] I may be allowed to remark here that certain experiments now in course of publication show very clearly that stimulation of human muscles causes a secretory cutaneous current directed from without inwards. This current is the true

the fibres in the neighbourhood of the section, owing to extension of the demarcation-current along the nerve.[1]

By this electrotonic extension we can explain—or for the part explain—the so-called "weak currents" of the longitudinal section.[2] A stimulus applied to the nerve near the line of

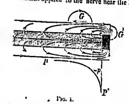

Fig. 5.

tion, according to the law of polarisational increment, should have a greater effect than when applied to points more remote, and this experiment shows to be the case. Finally, an excitation wave travelling along the nerve towards the cut end of it, according to the same law, gradually diminish before it disappears entirely in the area of section itself.

V. Concluding Remarks

The whole of the electrical phenomena of muscle and nerve, therefore, may be readily deduced from a few very simple positions. Irritable protoplasm responds both to destructive and to exciting influences by an electromotive sign. Altered substance takes on a negative potential with respect to the unaltered. This, together with the doctrines of internal transverse polarisation and of the polarisational increment of excitation, appears fully competent to explain all the facts hitherto observed.

That these fundamental doctrines have the closest reference to the whole life of irritable tissues no one will be disposed to doubt. Yet much examination will be needed to disclose the exact nature of the interdependence.

Although it must now be confessed that the theories which were based upon facts discovered more than thirty years ago have failed to withstand the criticism of a wider experience, the domain of animal electricity has not lost, but rather gained in interest. And the services of the man who not only discovered this region of physiology, but created the means of conquering it, and who made himself master of its most important fundamental features, are in no danger of becoming dimmed in our estimation by the theoretical changes we have been compelled to accept.

posed that nitric and nitrous acids, and their ammoniacal salts, were produced only by the electricity of heavy thunder showers. It is now evident that the reactions between vegetables and the atmosphere, under feeble electric tensions, are the most important, the smallness of the effects being compensated by their duration, and by the extent of the surfaces influenced.

These researches have attracted a great deal of attention in France, and other scientific men are investigating the subject. Among the forms of apparatus that have been devised for experimenting on the action of electricity on living plants, that invented by M. Celi appears to be one of the best. It consists of a large bell-jar, into which electricity is admitted in a very ingenious manner. An insulated metallic vessel is placed on a support about six feet high, and filled with water, which is then allowed to flow out by a very narrow tube. The vessel thus becomes charged with electricity, positive or negative, according to the state of the atmosphere,—commonly the former. A collector, formed of metallic wire, is attached to this vessel, and penetrates into the bell-jar, where it is connected with a crown of sharp metallic points for distributing the electricity. Under the bell-jar are placed plants in vessels communicating with the ground. The bell-jar is supported on glass, and air can be admitted or withdrawn through tubes arranged for the purpose. For comparison, plants similar to those under electric action are inclosed by another bell-jar of the same size without application of electricity, but otherwise treated in precisely the same way. On the 30th of July M. Celi sowed some grains of maize in the manner described. On the 10th of August the plants in the electrified air had a length of 17 centimetres, while those in the unelectrified air were only 8 centimetres long.

Further experiments are now in progress, the results of which we hope to report to our readers at a future time. That the electrical action is an important factor in the development of plant-life would appear to have been already proved, and when the *modus operandi* comes to be understood it is probable that it may suggest some important applications of electricity in practical agriculture. Electricity may come to the farmer's aid, as chemistry has already done; and "lightning fertilizers," warranted to stimulate plant-growth "at a shocking rate," may erelong be as familiar as guano and phosphates now are.

KEEP YOUR MILK-CANS CLEAN.

We have several times referred to the danger of spreading certain infectious diseases, such as typhoid fever, scarlet fever, etc., through the medium of the milk-can. Even a want of proper care in keeping the cans clean may prove the cause of sickness on the part of those who use the milk conveyed therein. Dr. John Muter, F.C.S., in an English sanitary journal, gives the following case illustrating this:—

I have been lately consulted by a gentleman, whose family suffered an attack of sickness and purging after partaking of the usual morning's milk, with the view, if possible, of tracing the cause of the attack. The quantity saved was unfortunately very small, and was delivered to me in the can in which it came, but a larger amount of the same ... which had been boiled, was also submitted ...

ELECTROMOTIVE FORCE.—RESISTANCE AND CURRENT.—I.

By J. T. Sprague ("Sigma.")

THE purpose of the present article is to develop the inter-relations of the three fundamental expressions and units of dynamic (or moving) electricity, to give to these somewhat more of definiteness than is usual in the ordinary text-books, and to do this mainly by showing what physical realities underlie the terms and formulæ used by electricians.

Of course, the text from which these practical lessons are to be drawn is the well-known formula of Ohm $\frac{E}{R} = C$. The current is proportional to the electromotive force divided by the resistance; or, employing the received units of the British Association system of measurement, $\frac{E\ \text{Volt}}{R\ \text{Ohm}} = C$ Veber.

The very first point to be considered is whether these symbols have any reality behind them. Are they mere mathematical abstractions, simple tools of thought, or are they concrete realities? Now, this is really a very serious question, because these scientific formulæ are now so extensively employed and so completely relied upon that they acquire a kind of imaginative actuality, just as the creations of popular writers do. Thus Scott's "Ivanhoe" is possessed, to most readers, of as distinct a personality as Richard Cœur de Lion, and probably the personality of the latter, notwithstanding the fact that he had an actual living existence, is built much more strongly upon Scott's "Ivanhoe" and "Talisman," than upon what are supposed to be the actual chronicles of history.

Now mathematical formulæ have just such a pseudo-reality. They may be mere idealities and yet true, and they may be given actual existence and become false.

I give an abstract form to the formula, and write $\frac{6}{2} = 3$. Here we have a well-known truth. But if I attach a concrete value to the figures the result may be mere nonsense; for instance $\frac{6\ \text{Sheep}}{2\ \text{Butchers}} = 3$?

In fact, the concrete values must be of one order, or must have a natural relation among themselves.

Now let us see whether and why the abstract $\frac{E}{R} = C$ represents concrete facts and truths. To this end we must clearly understand *what the symbols represent.* Of course everyone knows that E stands for Electromotive Force; R for Resistance; C for Electrical Current. But if these are three distinct actualities, concrete existences, how come they to hold among themselves the relations involved by the formula? E, then, is electromotive force. But what is electromotive force? A force tending to set electricity in motion; or, to use a better phrase, to set up that motion which we call electricity. Here it will be seen we have at once two considerations presented to us: an effect, the motion produced; a cause, the force producing the motion. Of these the first, the motion, is of necessity an actual thing, though we may hold different ideas as to what the thing itself really is. But does the force exist, that is to say as a special force? There are actual forces having real existence, such as the various attractions of which we may take gravitation as the type; these are, so to speak, self-existent—we know not their causes. But there are other agencies which we call forces, yet which have only a temporary existence; they are, in fact, simply transfers of energy.

Any agency may be called a force which is capable of setting up motion, or altering the conditions of motion in a mass of matter. Thus, if we take a ball of lead and let it fall, motion is imparted to it by gravitation: we may push the same ball of lead along a table, or by muscular energy hurl it to a distance; we may strike it as a cricket-ball is put in motion, by a percussive blow; or we may, by aid of a gun, set it in motion by means of compressed air or by the explosion of gunpowder. In all these cases motion is produced, and we may call the agent in each case a force. We may even embody all these agencies in one expression, and attribute the motion generated to the action of a "Mechanico-motive Force," the intensity of which we can measure by the amount of motion produced. Such an expression might be correct enough mathematically, but physically it would be a delusion, for only in one instance, that of gravitation, is there an actually existing agency, properly called a force, at work. But any mechanico-motive force can be compared to gravity, because all can be expressed in terms of the velocity which has been set up, or which can be imparted to a unit mass of matter in a unit space of time; the force of gravitation on this earth being such as to generate a velocity of 32 feet per second in round numbers, or an actual motion of 16 feet per second.

But gravitation, and all similar natural forces of the nature of attraction, are constantly acting (and such attractive forces as electricity and magnetism increase during their action, because the distance diminishes), and, in consequence, its effects are cumulative, and result in a regularly accelerating motion, while the other forms of force noticed are simple impulses, and set up a fixed velocity at the origin of the motion. We may, however, for some purposes of reasoning, ignore this property of gravitation, and consider only its unit action, as I shall do presently, in order to make some comparisons with electromotive force.

Now, then, what is electromotive force? When we dissolve zinc in a battery, this force makes its appearance. It is said by some to be due to the contact of the two dissimilar metals; that at the point of contact there is a sort of attraction or repulsion which decomposes the supposed natural or normal electricity, and sends the two halves to seek reunion through any roundabout or difficult path. But one thing is certain:—This force can do no work unless it is maintained by an equivalent supply of energy, and as a matter of fact easily proved, the degree of electromotive force produced is measurable in terms of the chemical actions which occur; and, speaking roughly, it is proportional to the difference of the tendencies of the two metals to combine with the radicals of the acids acting; that is to say, to the heat generated by these metals in the act of combination.

But if we expose the junctions of two different metals to heat, we find electromotive force set up in degrees depending (1) upon some inherent property of the metals (which has an appearance at all events of supporting the contact theory of its origin), and (2) upon the different temperature produced, which means in fact the quantity of energy which can be thrown into the circuit.

Again, if we move a conducting body in the neighbourhood of a magnet in certain directions, we find electromotive force in action: here no contact of different metals exists, to account for the fact; but an amount of energy is absorbed proportionate to the forces.

On examining the various modes of developing electromotive force, we find in fact that it always involves an absorption and distribution of energy, and that the same principles are involved as in the case of what I have called mechanico-motive force; but we find in no case (except apparently in the attractive force of static electricity) any force analogous to gravitation, or to any of the natural attractive forces. Electromotive force is constantly acting upon the circuit, but it has no accelerating action. We are therefore forced to the conclusion that it has no actual existence, but that, like mechanico-motive force, it is simply an application of energy.

E, then, in Ohm's formula is simply an expression, valuable in use for calculations, but symbolising not a thing, but a value, a quantity of energy applied in a specific mode, to produce a definite molecular disturbance in a conductor and a propagation of electrical action. This will be seen more completely by-and-by.

A New Phenomenon in Statical Electricity.—M. E. Duter, in a paper read before the French Academy in December, showed that when a Leyden jar is charged with either positive or negative electricity, its internal volume increases, and that this effect is a new phenomenon, unexplainable by either a theory of an increase of temperature or of an electrical pressure. The experiment was performed by means of a flask-shaped Leyden jar, with a long tube attached to its neck, and containing a liquid which served as the inner armature. The author's attention had been called to the fact that this phenomenon had been observed 10 years ago by M. Gori. His researches, just made public, leave no doubt of the accuracy of M. Duter's view, that the glass of the jar really expands. According to the theory of elasticity, the effect of an internal pressure in a hollow sphere is in the inverse ratio of its thickness. M. Duter, therefore, had three flasks made of the same volume, but of thicknesses of 4 mm., 0.8 mm., and 0.5 mm. respectively. They were filled with water and enveloped with tin foil. Each carried a capillary thermometer tube, in which the variations of the hight of liquid served to measure the changes in volume due to electrification. He found that these changes were imperceptible in the thick glass, very marked in the flask of mean thickness, and rose to 30 mm. in the thinnest. The variations in volume were very nearly in inverse ratio of the square roots of the thickness.—*Scientific American.*

ELECTROMOTIVE FORCE.—RESISTANCE AND CURRENT.—II.

By J. T. Sprague ("Sigma.")

We have now to consider the meaning of the second symbol R, or Resistance. If we have at command an inexhaustible supply of water at a given height, say, for instance, the Falls of Niagara, that body of water continues falling as long as it is not prevented from doing so, and it is evident that even a small height would give an infinite current of water across an infinite space. But let us have the power of controlling our Niagara (and one advantage mathematicians possess over experimental philosophers is just that very thing—they can assume any condition of things which suits their purpose). Let us provide a measured outlet, which will permit only a fixed current of water to pass. We may now consider this condition of affairs from two points. Looking at the actual current generated, we may speak of the conducting power or capacity of the outlet. Looking at the restraint put upon the power of the source, we may speak of the resistance presented to its action. Each mode will be correct to some extent; both can be made to give the same results as to the actual flow of water. Now let us give this figure definiteness by reducing it to units of measurement. As gravity will cause a fall of 16 feet per second, let that be the unit value of the mechanico-motive force which I now represent by the symbol M. This force will, therefore, generate a current of 16 feet of water per second; but to give any value to that statement we must know what is the area or section of the current of water. One square inch 2 feet in height is nearly 1lb. of water—it is actually ·980; but, availing ourselves of the mathematical license, we will call it 1lb. We thus get two other units, 1 square inch, the unit of conducting capacity, and 8lb. the unit quantity or current per second. Let us symbolise these by A or area for conducting capacity, and the unit flow of water or current by C. Then we have:—

Mechanico-motive force M acting through conductor A producing current C,

$$M \times A = C,$$
$$16 \times \cdot 5 = 8,$$
$$\text{or } 8 \times 1 = 8.$$

A is ·5 or ½ because it is, of course, related to the terms of M by the necessities of any unit system and M, although originating in gravitation, is here not a natural, but a mathematical force, based upon the action of gravity during one second, but isolated from the accelerating force of real gravity. It is just a force which, acting in the unit conductor of 1 square inch, produces a current of 8lb. of water per second; we may call M = 16 and A = ·5 because the 16 feet in length contain and transmit the unit 8lb. current; or we may call M = 8 and A = 1 because that force and conductor will generate (by actual gravity) a velocity of 16 feet per second, and therefore a current of 8lb. For the convenience of having the unit conductor A = 1 the latter mode is preferable.

Now M remaining constant, the flow of water C will be proportionate to A. If we provide a double conductor we have M × 2 A = 2 C or 8 × 2 = 16, and so on.

But it is an arithmetical fact that, if instead of multiplying by a number, we divide by its reciprocal, the same result is attained. The reciprocal of a number is of course 1 divided by that number.

Now let us take the reciprocal of A, our unit of conductivity, and we have 1 ÷ 1 = 1 and 1 ÷ 2 = ·5. If we now symbolise this reciprocal of the conducting power by R used as a divisor in place of A used a multiplier we get the formula

$$\frac{M}{R} = C \quad \frac{8}{1} = 8 \text{ and } \frac{8}{\cdot 5} = 16.$$

But this is simply Ohm's formula, and the fact of the matter is that what is called electrical resistance is in truth simply the reciprocal of the conducting capacity. If this were all, it would be merely a matter of names; but, unfortunately, it involves a great confusion of thought and much practical misconception. The electrical unit of R or so-called resistance, the Ohm, is in truth a conductor of definite capacity perfectly analogous to our supposed square inch pipe 16 feet long, and, in fact, a wire carrying an electric current bears many close physical analogies to a pipe conveying water. We always call wires conductors, and then instead of estimating their value in terms of their conducting capacity, we measure and think of them in terms of their resistance.

The consequence of this, which is really a mere matter of form, is that, as is so common in law and theology, the form becomes a reality, and upon it is based the monstrous doctrine, now calmly accepted by electricians, that a conductor offers no more resistance to a large current than to a small one. Hence it is also that the laws of transmission of electricity are supposed to be quite different from those of, say, water; whereas the fact is that they are identical, and that this mistaken idea is due simply to the giving of the name "resistance" to what is only a mathematical fiction.

True resistance is that which opposes a force doing work and which needs the expenditure of energy to overcome it: that resistance we meet with in our conductors, and it is, as in all other similar cases, with a given conducting capacity (that is in a fixed conductor) proportionate to the square of the current passing: that molecular disturbance which results in the heating of the conductor is the true electrical resistance analogous to friction and other resistances in mechanics: that which is called resistance in electricity is simply an artificial figure, the reciprocal of the conducting capacity and the analogue of the dimension of pipes in hydraulics.

In the third element of our formula, C, or Current, we have something actual, although by a strange perverseness this one thing which is an actual natural fact, obvious to the sense, and furthermore the very one which is the most important, because it is the basis of all electrical work, is the one which the devisers of our systems of measurement passed by. The electric current has definite relations to nature, it has a fixed equivalent in connection with chemical actions, it has a definite relation to magnetism, it does a fixed quantity of work, and generates a fixed amount of heat. All these reasons point to this, the measure of current, as the one natural base upon which the whole system of measurement should be constructed. But this was overlooked, and the system of measurement, instead of being connected to natural laws and the atomic system of matter, is based upon purely artificial mathematical considerations. It is true that, as a consequence, it is really a system of measurement of energy, but then energy would have been equally measurable had the natural unit been employed as the foundation. The only difference would have been this. The unit adopted is what is called the absolute unit, the metre-gramme second; that is to say, the force which would in one second give a velocity of one metre per second to a mass of one gramme.

This being fixed, all other forces and actions may be expressed in it, but necessarily by some fractional value. Thus the force of gravitation is equal (at London, that is to say, gravitation varying at different parts of the earth) to 9·811 such units, and in like manner the heat and other units of energy may be expressed in absolute units, and so can the chemical and magnetic relations of electricity. But had the system of measures been based upon the natural relations of electricity, just such a fundamental unit could have been used for other purposes, only it would have contained within itself one fractional part; the measure of length, for instance, would have been something more or less than a meter, but once defined and being merely an instrument of calculation, the unit would have been just as serviceable as the actual metre-gramme second, while the relations of energy and matter would have been rendered apparent.

In my book, "Electricity: Its Theory, Sources, and Applications," I have already pointed this out, and, in fact, I found myself compelled to use such a unit on my own authority, because my aim throughout was to make manifest the natural physical basis and relations of electricity, which are left wholly out of sight in the now fashionable arbitrary and mathematical teachings on the subject. The unit I used was for practical reasons based upon the grain atomic weights, 1 grain of hydrogen in 10 hours. A similar unit of electrical quantity, based on the metric atomic weights, is commonly used by Continental writers, viz., one-tenth of a gramme of hydrogen, and whether one hour or ten, one gramme, or one-tenth is used, is merely a question of placing the decimal point, and of the actual physical value of the principal unit and its multiples. It so happens that the actual absolute unit closely approximates to such a system, and I believe that in this fact there exists a grand natural truth, at present hidden from sight, purely by the arbitrary unit adopted, this truth being the fundamental connection of matter and energy by which energy is related to the atomic system of matter. Our measures are not as yet exact enough for full working of this out, but, so far as is at present known, the Weber unit of current, which is ·01 of an absolute unit, releases ·00001022 of a gramme of hydrogen; so that an absolute unit itself represents ·001022 of a univalent atom of matter.* It may well be that various errors of observation result in an error of 2 per cent., seeing that there is a good deal of uncertainty about the absolute value of the Ohm and other measures of resistance. But if our mathematical masters had but based their system upon this actually existing, easily measurable thing—the chemical action of electricity—instead of building it up from a purely theoretical and arbitrary basis, much less experimental work than has been given to the valuing of the Ohm would have established the exact relations of resistance and energy to chemical combination, and we should have had a unit of energy equivalent to 1 gramme (or any decimal submultiple) of univalent atomic affinity. *Matter and energy expressed in one unit.* Who can foresee what vistas of knowledge such a standpoint would present?

* I take the opportunity here of mentioning that owing to the confusion caused by some writers using the metre-gramme absolute unit, and others having most needlessly employed a centimetre-gramme system, I made a mistake in the table, p. 212 of my book. The value in water of the Weber is ·09322 instead of ·0932. As a consequence, all the values of the last column require an additional 0. This is also the case with the different values given in different books to the B.A. units, as to which frequent inquiries have been addressed to me.

88

Electricity in Air.—Recent experiments of M. R. Nahrwold tend to demonstrate that it is the dust in air and not the air itself which becomes electrified. When air is sifted of dust by means of glycerine, it takes only a very feeble charge. M. Nahrwold also remarked that positive electricity discharges itself more readily in air than negative, a result contrary to those of Wiedemann and Ruhlmen, and we think also of Thomson. During the electric discharge, when viewed by the light of the mechanical theory of gases, would seem to show that the discharge, besides increasing the *vis viva* of the moving molecules, also increases the *vis viva* of the oscillatory motion of the ether envelopes. Different spectra got from different points in the width of the gaseous tube are therefore not to be referred only to the different temperatures of the gas, but to the amounts of electricity of which the passage causes the oscillation of these ether envelopes.

An electric water-level Indicator has been fitted up by the Silvertown Company at the New Water Works, Leamington. A rise or fall of the water level applies the positive or negative pole of a battery to the indicator for a certain time, and causes the hand to indicate the new level in feet. A similar instrument, designed by the Postal Telegraph Engineers, was fitted some months ago to a reservoir of the Nottingham Waterworks Company, and has given great satisfaction.

Animal Electricity.—In a remarkable lecture delivered before the Medical Society of Zurich on February 2nd, 1878, and published in our contemporary, *Nature*, for April 17th, Dr. L. Herman summarises that "the whole of the electrical phenomena of muscle and nerve may be readily deduced from a very few simple propositions. Irritable protoplasm responds both to destructive and to exciting influences by an electro-motive sign. The altered substance takes on a negative potential with respect to the unaltered. This, together with the doctrines of internal transverse polarisation, and of the polarisational increment of excitation, appears fully competent to explain all the facts hitherto observed."

LES
MOUVEMENTS MOLÉCULAIRES
ÉLECTRIQUES

May — 79

C'est un désir qu'on entend souvent exprimer, que celui de pouvoir s'endormir pendant un siècle, pour jouir d'un seul coup au réveil de la masse des découvertes, des progrès de toute nature accumulés pendant cette longue suite d'années. L'électricité est assez féconde pour fournir dans le cours naturel du temps des joies scientifiques de cette espèce; à certains moments, des expériences, jusque-là isolées et qui semblaient plus curieuses que fertiles, se rapprochent, se complètent, et, par leur groupement, ouvrent soudain de vastes perspectives, et mettent sur la voie des conséquences les plus étendues.

Dans cet ordre d'idées, il faut signaler les expériences relatives aux mouvements produits par l'électricité.

Il y a longtemps qu'on a obtenu des mouvements à l'aide de l'électricité, les attractions, les déviations des aiguilles

87

aimantées, les transmissions télégraphiques, etc., datent déjà de loin; mais dans ces effets on passe par l'intermédiaire de l'action magnétique, et bien que celle-ci ne soit, en somme, qu'un état particulier de l'électricité, ces mouvements peuvent n'être pas considérés comme résultant immédiatement de la variation de celle-ci.

Il ne s'agit pas non plus des dilatations qui peuvent naître de la chaleur produite par l'électricité; dans ce cas, il y a transformation du fluide, s'il est permis d'employer ce terme qui n'a plus beaucoup de sens; il s'agit de mouvements, d'effets mécaniques produits dans les corps sans intermédiaire, liés directement et immédiatement à l'électricité.

Ces effets, bien que d'une extrême importance, sont naturellement très-petits en grandeur, et on ne doit pas s'étonner qu'ils aient échappé longtemps dans leur généralité à la sagacité des savants.

C'est la vibration sonore qui, la première, les a dénoncés. On aurait pu s'y attendre, on savait bien que des variations de forme que nos instruments de mesure sont impuissants à constater, peuvent, en se répétant, produire des sons très-appréciables, qui en rendent sensible l'existence. Vers 1837, un Américain, M. Page annonça qu'un fil de fer entouré d'un conducteur isolé produisait des sons lorsqu'on faisait passer des courants fréquemment interrompus dans ce conducteur. Cette très-curieuse expérience fut reprise, discutée par Wertheim, de la Rive, et il fut établi que, sous l'action de ces courants répétés, le fil influencé subissait des variations de forme donnant lieu à des vibrations sonores. On saisissait ainsi le mouvement électrique; sans aucune de ces actions qu'on nomme mécaniques, on produisait un déplacement de matière rendu sensible par les sons émis. C'est sur cette propriété que fut fondé le premier en date des téléphones, celui que Reiss construisit en 1860 et dont le récepteur consistait en un fil de fer tenu par ses deux bouts et entouré d'une bobine où passaient des courants interrompus par les vibrations sonores du transmetteur.

Une autre forme curieuse des vibrations résultant du seul passage de l'électricité est due à M. Varley, qui construisit un téléphone où le corps vibrant était un condensateur formé de lames conductrices et isolantes alternées et renfermé dans un tambour renforçant. C'est cette expérience reprise et ingénieusement variée par MM. Pollard et Garnier qui a donné naissance au singulier condensateur chantant qui causa tant d'étonnement l'année dernière.

Mais il n'est pas nécessaire de recourir à la forme délicate des vibrations sonores pour accuser les mouvements moléculaires dus à l'électricité. M. Edison en a donné dans son électro-motographe une application qui les rend sensibles d'une façon très-frappante. On sait que cet appareil se compose d'une pointe métallique sous laquelle passe, d'un mouvement continu, une bande de papier imbibée d'hydrate de potasse. Le mouvement du papier trouve naturellement une certaine résistance dans le frottement exercé sur la bande par la pointe de métal. M. Edison a reconnu qu'à chaque passage d'un courant dans la pointe, ce frottement change de valeur. Il se produit dans les corps en contact une modification dans l'état des surfaces telle que la force retardatrice n'est plus la même, Edison a employé ce mouvement à produire des signes dans son électro-motographe, et des sons dans son curieux récepteur téléphonique (1).

Les mouvements électriques sont ainsi clairement manifestés; mais ils sont susceptibles d'une démonstration plus nette encore. Dans des expériences récentes, mais dont M. Govi a réclamé la priorité, M. Duter a fait voir qu'un vase rempli de liquide n'a pas la même capacité quand ce liquide est électrisé et quand il ne l'est pas. Il a établi que dans une bouteille à col très-fin, si l'on électrise le liquide qu'elle contient en la tenant à la main, de façon à constituer une sorte de condensateur, le niveau dans le col change brusquement si l'on vient à décharger l'appareil. La forme du vase subit une altération qui a pu être mesurée. Il convient de citer aussi, comme manifestation curieuse de mouvements de même genre, les expériences par lesquelles lord Raleigh a fait voir que la forme d'écoulement d'une veine liquide est modifiée par son état électrique.

Les mouvements moléculaires dus à l'électricité sont ainsi rendus directement visibles et mesurables, et de ces expériences jointes aux faits précédents où on les voit manifestés indirectement, on serait déjà en droit de conclure que toute variation électrique entraîne une variation moléculaire, mais on en peut fournir bien d'autres preuves.

D'abord la démonstration par l'inverse qui est très-probante: si l'électricité produit par ses variations des mouvements moléculaires, réciproquement les mouvements moléculaires doivent amener des variations électriques. Or, en 1856, les travaux de M. du Moncel ont établi que dans les corps médiocrement conducteurs toute variation de pression entraîne une variation de conductibilité et sur ce principe, repris et généralisé par lui, Edison a fondé le transmetteur de son téléphone. On sait que, dans cet appareil, les vibrations de la plaque parlante sont transmises à un bouton de charbon à travers lequel passe un courant, et que toutes les vibrations produisant de légères pressions sur le charbon amènent des variations électriques. C'est sur le même principe que repose son micro-tasimètre où les dilatations très-faibles d'un corps sont rendues sensibles par la pression qu'il exerce sur une plaque de charbon traversée par un courant.

Le microphone de Hughes nous montre aussi un courant influencé par les différences de pression de deux corps vibrant l'un sur l'autre.

On trouvera encore une curieuse manifestation des mêmes faits dans l'électromètre de Lipmann et dans le téléphone à mercure de Bréguet qui repose sur le même principe. Dans ces appareils, on interpose dans un circuit deux tubes renfermant du mercure. On sait que ce métal, à sa surface libre, présente une forme bombée, une surface courbe que l'on nomme ménisque. M. Lipmann a montré que, si par un moyen mécanique quelconque, on modifie la forme de l'un de ces ménisques, le courant en est affecté et reproduit dans le deuxième tube la déformation réalisée dans le premier. Cette expérience est remarquablement concluante, puisqu'elle

(1) Voir ci-dessus l'article « *Nouvelles découvertes en téléphonie* » Th. du Moncel.

…ous montre l'action mécanique produisant la variation électrique, et celle-ci à son tour rendant le mouvement qu'elle a reçu.

Dans tous ces appareils, des modifications moléculaires très-petites, résultant de pressions extrêmement faibles, sont immédiatement manifestées par des changements très-sensibles dans le courant. D'où il résulte sans aucun doute la preuve de la liaison intime et absolue qui existe entre la constitution intérieure d'un corps et son état électrique.

Ces recherches ont pris une extension très-grande et une importance de premier ordre depuis l'invention des téléphones parlants. Depuis qu'il a été reconnu que dans l'appareil de Bell on pouvait supprimer la plaque en fer sans détruire le son; depuis qu'il a fallu, par conséquent, renoncer aux attractions magnétiques auxquelles on avait d'abord attribué les vibrations, la théorie de ces appareils a dû entrer dans une autre voie, et on a reconnu là de nouvelles et générales manifestations des mouvements moléculaires électriques.

Les études et les expériences remarquables en ce sens sont si nombreuses, qu'il ne faut même pas essayer de les résumer ici; signalons seulement les résultats frappants obtenus par M. Ader, d'où il résulte qu'un fil quelconque parcouru ou entouré par le courant, en reçoit des vibrations si nettes qu'elles peuvent, convenablement recueillies, transmettre la parole, complément bien remarquable de l'expérience de Page qui a été l'origine de toutes ces recherches.

Signalons les faits si curieux qui ont établi qu'un liquide même peut servir de récepteur téléphonique, et qu'il éprouve par le passage de l'électricité des ébranlements assez sensibles pour être recueillis et transmis à l'oreille.

De tous ces faits on conclut qu'une liaison absolue existe entre la situation relative des molécules d'un corps et son état électrique, et qu'aucune variation si faible que ce soit ne peut se produire dans l'un de ces éléments sans que l'autre en soit affecté suivant une loi régulière.

Ce résultat est d'une haute importance, en ce qu'il semble nous offrir un moyen de pénétrer cette constitution intime des corps dont la connaissance nous est si difficile. Dès à présent il met dans un curieux relief l'extrême instabilité de cette constitution. Il en résulte, en effet, que si les molécules des solides se meuvent dans de très-étroites limites, elles s'y déplacent avec une extrême facilité, et sous l'influence d'actions excessivement faibles. Leur situation relative, la forme en un mot des corps solides, ne peut, sans des forces importantes, subir des modifications sensibles; mais elle en subit de très-petites sous l'action des plus petites forces, et, bien que nous ne le voyons pas, est en réalité dans un état de continuel changement.

Au reste, il est généralement inutile de chercher à prévoir à l'avance les résultats qui sortiront d'une nouvelle série d'études; ils sont quelquefois bien différents de ce qu'on attendait; ce qu'on peut seulement presque toujours affirmer sans crainte, c'est qu'ils existeront, et à cet égard l'ensemble des faits qui viennent d'être rapidement rappelés offre toutes garanties et présente aux recherches un champ qui ne peut manquer d'être fécond.

LES MESURES ÉLECTRIQUES

Comparaison pratique des mesures de l'intensité du courant

Une des méthodes les plus simples dont nous puissions recommander l'usage, est celle qui a été proposée la première fois par Jacobi et qui consiste à recueillir la quantité de gaz inflammable produite par la décomposition de l'eau acidulée.

Suivant cet éminent électricien, le nombre de centimètres cubes obtenus en une minute représentera numériquement la force du courant.

Il n'est pas difficile de deviner quelles sont les précautions nécessaires pour que ces comparaisons aient un degré de précision suffisant pour une pratique éclairée.

On nous dispensera certainement de faire remarquer qu'il faut opérer avec des voltamètres identiques, en employant de l'eau distillée, toujours acidulée avec la même quantité d'acide chimiquement pur, etc., etc.

On sait que le volume des gaz varie en raison inverse de la pression et qu'il augmente par suite de la chaleur. Il faudra donc réduire par le calcul la quantité de gaz recueillie, jusqu'à ce qu'elle soit sous la pression normale de 76 cent. et à la température normale de 0° centigrade.

Mais, malgré toutes les précautions les plus minutieuses, il n'est point possible d'obtenir une exactitude indéfinie.

En effet, le mélange gazeux formé d'un volume d'oxygène contre deux volumes d'hydrogène se dissout en partie dans le liquide, et la fraction ainsi absorbée varie, suivant la température et la pression atmosphérique. En outre, une portion plus ou moins grande du gaz produit par la décomposition de l'eau acidulée adhère aux électrodes de platine, par suite de la polarisation, qui est d'autant plus énergique que le courant est plus fort ou qu'il agit pendant un temps plus ou moins prolongé.

Deux autres appareils, également simples et aussi souvent employés, sont les boussoles dites des tangentes ou des sinus, instruments trop connus pour qu'il soit nécessaire d'en donner ici une description.

Il est inutile d'ajouter que, pour donner aux comparaisons faites avec ces instruments une valeur sérieuse, il faut se mettre dans des conditions identiques et, par conséquent, définir la force directrice du globe, dans la station où l'on opère, au moment des observations.

En effet, c'est à cette dernière que l'énergie des courants est rapportée, à l'aide de la loi du sinus ou de la tangente, suivant que le limbe dans lequel passe le courant est mobile ou ne l'est pas, et qu'il reste dans le plan du méridien ou passe dans celui que l'aiguille de bons ole prend lorsqu'elle est soumise à l'action du courant.

Le galvanomètre doit être choisi de telle sorte, que la résistance qu'il oppose soit négligeable.

En conséquence, il faut un fil court et gros, quand le courant à mesurer est de faible tension.

Au contraire, il faut un fil long et fin, replié plusieurs fois sur lui-même, lorsque le courant est de faible quantité, mais de grande intensité.

On comprend qu'il ne soit pas très-commode de ramener les unes aux autres les mesures prises avec des instruments si différents.

La difficulté est d'autant plus sérieuse que la construction des appareils entre pour beaucoup dans les résultats obtenus.

Non-seulement il faut se préoccuper de la manière dont l'aiguille est placée dans sa chape, mais encore de l'intensité absolue de son magnétisme qui varie avec bien des circonstances difficiles à déterminer. Enfin, le diamètre du cercle sur lequel les fils de cuivre sont enroulés influe lui-même d'une façon appréciable sur les indications.

Toutes ces considérations font qu'il ne faut attacher qu'une médiocre importance à la rigueur exa…

ELECTROMOTIVE FORCE—CURRENTS AND RESISTANCE.

[15718.]—I AM under some little difficulty in replying to Mr. Moberly, 15686, p. 263, because where I am at present I have not with me the articles referred to, or a single book relating to the subject, not even my own: I can, therefore, only treat it generally at present. I will leave out of consideration therefore my thesis that the Volt, Ohm, and Veber are the same quantities of energy, but I may remark thereon, as well as concerning other points, that everything has several sides; truth takes account of all the accessible sides, although for special purposes now one and now another aspect may be most important. My purpose was to indicate a very important part of the electrical system, which is entirely ignored in the usual way of dealing with it. Now, Mr. Moberly says that I repeatedly use force and energy as interchangeable terms. The distinction is so clear in my own mind that I doubt that; but then that distinction is only of recent growth, and the terms are colloquially so similar in meaning that there is a borderland in which the real distinction is lost; in some such slight matters I have noted instances in which I should change the terms on revision, though the change would have but little significance. But my very object in the articles referred to was to show that from a certain aspect force and energy are identical. For mathematical purposes, that is, in the legitimate field of mathematics—calculation—the expression of facts and operations in formulæ, it is essential that force and energy be kept as two distinct conceptions, having each its own symbolic expression and its own function in formulæ. None the less, force when acting becomes energy, and energy often has to be formulated as a force. What I aimed at doing was to make manifest the results following upon the consideration of force acting in a unit space, by which the abstract force is converted into concrete energy. Why did I do this? To show in what manner energy is converted into mathematical force. It is because Mr. Moberly, in common no doubt with many others, has missed this that he charges me with this "fundamental error; a quantity x of force can never be equal to or identical with a quantity y of energy." Now the error here is, I think, his own; there cannot exist

a *quantity x of force*. Force—the true mathematical force—exists not as a quantity, but as a degree. The instant you express force as a quantity it becomes energy. Now, Mr. Moberly in his following explanations shows correctly the relation which does exist between force multiplied by distance and energy, only he misses the fact that it is this very relation I was employing in my articles.

I do not feel myself called upon to defend my description of the values of the Volt, Ohm, and Veber in absolute units. *I gave those values as the report of their originators, the B. A. Committee, gives them.* Mr. Moberly may be quite correct in his conception of them from the abstract mathematical standpoint, but he must settle that with the mathematicians. My object is simply to make the subject intelligible to ordinary people, and to show what actual natural truths underlie the mathematical theory. But I have none of that "contempt for mathematics" attributed to me. They are invaluable in their own sphere. I only insist that formulæ are not final truths; that their meaning, as well as their use, should be understood, and that they must not be regarded as explanations of nature's mode of action when they are only artificial modes of calculating her results. Hence, therefore, I never professed to reject them as untrue. Let us admit them as true mathematically; then Mr. Moberly says they become true physically, if we assume conventions in accordance with the definitions. Be it so; we then come to the question what are the true conventions? The mathematicians prefer to express them as $L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-2}$, and so on. But satisfactory as these may be, there are some people who humbly whisper, Yes, that is true, no doubt; in fact, it must be so, *but what does it mean?* Now it is my ambition to answer *that* question, and if Mr. Moberly will shift his view to my standpoint he will see that I do this. The Volt is a force: it is not energy; yet it is defined by dimensions as above of space, mass, and time, and this combination *is energy*. The definition implies the *quantity of energy* which under given conditions constitutes a definite *degree of force*, or, in other terms, this definite degree of force acting in those dimensions generates that quantity of energy. In this sense, then, force and energy are the same thing; so that I only ask Mr. Moberly to assume my convention in accordance with *my* definition, and what I say is that he will then see some aspects of truth not visible from his own standpoint.

Gravitation is, as far as we know, an actually existing force. Head of water is a form of gravitation, and is a force definable by its pressure or potential. In that definition it is abstract—it is a degree, not a quantity. In like manner steam pressure is a force; pounds per square inch is a degree, not a quantity; but this is a mathematical, not a real force. It is dependent for its existence upon the *quantity of energy* concentrated within given dimensions. If we combine with steam pressure one dimension, area of piston, we have energy as pounds per space traversed; if we add this second dimension we have energy in foot-pounds. So if we add a corresponding dimension to head of water, which itself includes one dimension, viz., a unit area corresponding to the piston surface, we have gravitation expressed as energy. Now I hold as to electricity certain views:—

1. Electricity is not a fluid or an existing thing, material or etherial.

2. Electricity is not a force. It does not resemble gravitation in having an inherent existence.

3. Electricity is energy charged upon material molecules. It resembles heat and motion.

My object, then, was to trace out the mode in which energy becomes force in the electric circuit, and is correctly so expressed in mathematical formulæ, to discover, in fact, its analogy with energy developed as force in the steam-boiler. I have long worked at this with more or less success, till at last it occurred to me that the analogy was to be found in head of water. That analogy has long been employed as relates to tension or potential, but its true bearing has never before been observed so far as I know. When I saw that the square root of head of water fulfils in hydraulics exactly the same function as electromotive force does, as the Volt in electricity, I saw that the laws of the current of electricity and of liquids are identical, instead of being, as every one has always said, quite different. I have long foreseen that it must be so, but I have only now been able to prove it. That, and the truth that resistance, as defined electrically, is a misnomer, are the real subjects of my three articles, and I await with some little curiosity to see who is going to attack those heresies of mine—heresies and paradoxes to-day—truths accepted of all to-morrow.

Sigma.

EXTERNAL RESISTANCE AND INTERNAL CURRENT.

[15791.]—THERE is one part in the otherwise correct letter of "Humble Bee," 15717, p. 290, which I think will be misleading to many readers who are not well acquainted with the subject; it is this.

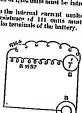
"To reduce the current flowing through a galvanometer to one-twelfth of its strength, the galvanometer must be shunted, with a resistance of twelve units, the galvanometer resistance being 132 units."

This gives one the idea that if the internal current was not in question, such would be the way to reduce the current in the galvanometer. The result of such an arrangement would be this.

The current in the galvanometer would be *unaltered*, while the internal current would be increased twelve times.

To reduce the current flowing in a galvanometer of 132 units resistance to one-twelfth of its strength, a resistance of 1,452 units must be introduced in the circuit.

To keep the internal current unaltered, a shunt with a resistance of 144 units must be inserted between the terminals of the battery.



B, battery; G, Galvanometer; R, resistance coil; S, Shunt.

H. Dominy.

ARTICLES.

ELECTROMOTIVE FORCE.—RESISTANCE AND CURRENT.—III.

By J. T. Sprague ("Sigma").

USING the received system, we can calculate the conditions of the electric circuit and current, by means of the formula of Ohm, employing either the absolute system of measures or the practical system of the British Association usually employed. I do not propose to treat of the absolute system, because it would of itself take up an entire article. The practical system is based upon it as the units are large multiples of the absolute unit.

The unit of electromotive force is the Volt, named after Volta, of the value of 100,000 absolute metre-gramme-second units. This value was selected because it is pretty close to the force of the Daniell cell, which has long been employed as a unit of electric force. Electromotive force is a theoretical absolute force resembling a pressure or a tension in that it is abstract, and means nothing till its area of action is defined. Hence it is independent of the dimensions of its source; an enormous electromotive force can be developed by a small electric machine, and the electromotive force of a cell of a fixed type is the same whether the cell be large or small. This is readily seen by opposing them to each other, and questions are so frequently asked on this point that I will describe a simple but very striking experiment I have often used to illustrate it. Take a small copper wire and the smallest strip of zinc which can be cut; wrap the latter in 2 or 3 folds of blotting paper, and fix them on a strip of wood as a support. Dip them in the zinc solution of a Daniell's cell so as to soak the paper, and then place them in a vessel containing solution of sulphate of copper; connect the copper wire to the copper of a large Daniell cell, and the zinc to the zinc, inserting a galvanometer in one of these connections. No current will pass, though if the cell and the micro-cell are connected separately to the galvanometer, it will show that the large cell can furnish a current hundreds of times greater than the little one. The reason of this is shown in the formulæ, thus—$\frac{E-e}{R} = C$. Now, if E and e are of equal value, they negative each other, and there is no force in action. Should two cells of different forces be so opposed, the force in action is the difference between them. Thus, in electro-metallurgy, there is usually what is called "Polarisation" set up in the depositing vat when the solution near the anode is saturated with metal, and that near the cathode exhausted; then there is a tendency to redissolve the cathode, and this sets up an electromotive force opposed to that of the battery; then the formula comes into action, and the current is reduced. If in these circumstances you have a galvanometer in circuit, you will see this reduced current. Now if you stir the liquid, so as to equalise the solution, you will see the galvanometer instantly mark an increase of current. This is one reason (not the only one) why it is advantageous to have the objects in motion while deposition is going on.

The Volt is also the unit measure of tension or sum of + and − of tension (and of potential or difference of potential—more fashionable names for the same thing), which are the first products and evidences of the presence of an electromotive force. In fact, tension is very often compared to pressure in the form of head of water, though the comparison is not quite correct, as double tension doubles current, while double head of water acts in a different proportion, because in that case the same force, gravity, is acting in both heads, while a double tension implies a doubled force. But when we look behind the names of things and forces to what they really represent, we often find hidden meanings. Head of water is pressure in one sense, but, as it also represents the height through which the water falls under the influence of gravity, it is also equivalent to the energy due to that fall. Head of water is therefore in one sense a force, and a force is measureable by the velocity it can generate, and head of water, as is a well-known fact in hydraulics, generates velocity, that is to say current or flow of water in the ratio of the square root of the head. But, on the other hand, velocity implies also energy in the ratio of its squares. Hence, as energy due to head of water generates a velocity in the ratio of its square root, so velocity in its turn returns that energy in the ratio of its squares. Hence M, our symbol of mechanico-motive force, is seen to mean the same thing as the square root of head of water, and consequently 2M, while called a double force, means energy supplied or expended in fourfold degree, or as the square of M. In like manner E, the symbol of electromotive force, is but an expression for the square root of the energy supplied to the circuit. This is to be seen at once in batteries where if we use two cells, which means 2E, to double the current, four times the quantity of zinc is consumed, and consequently four times the quantity of energy supplied. Here, then, we have at once the reason why current varies in Ohm's formula directly as the electromotive force. E is a symbol for the square root of the energy; C, current or velocity, expresses the square root of the energy expended in carrying the current through the resistance.

The unit of resistance, the Ohm, fairly named after the man who really introduced the idea of resistance in its present form, is equal to ten million absolute units of force. It was selected as the nearest multiple to the largely employed unit of resistance, the Siemens mercury unit, which is a square centimetre of mercury 1 metre long. Now this unit itself is obviously a conductor of defined capacity; it is a most round-about way of dealing with it to call it a resistance. The analogy is perfect between it and the square inch conductor of water which I employed to illustrate the true nature of resistance.

The Ohm is, in fact, a wire of definite conducting power, but the actual Ohm, as used, doubtfully fulfils the intentions of its producers, there being good reason to believe that it differs possibly more than 1 per cent. from its intended value. At all events, the Ohms in actual use differ a good deal among themselves, partly from difficulties in adjusting them at first, and partly from changes which take place in the wires. They are usually made of German silver because its resistance is considerable, and does not change largely with variations of temperature. But German silver is a brass in which nickel to some extent replaces zinc. Brass is subject to some very strange changes, and probably German silver is so also, though not to the same extent. In fact, I have only had one sample of German silver wire (and that of low quality containing little nickel) assume the extremely brittle state which is a common thing in brass wire. In this particular case the wire, No. 35, fell into pieces on unwinding, though it was quite soft when wound on the reel.

To obtain resistances, either Ohms or multiples, it is necessary to measure the several wires against a standard, by means of the Wheatstone bridge. It is an operation involving an amount of patient labour and skill honestly applied, such as no one can conceive who has not himself taken the work in hand.

We have already seen that what is called electrical resistance is misnamed. The Ohm, the unit of this measure, is really a defined conductor which allows a current of electricity of definite amount to pass under the defined unit force. But it has a definite ratio to energy: all conductors, such as pipes carrying water, really present a resistance; in the case of water this is due to the friction of the particles of water upon each other and upon the surface of the pipe; in the case of electricity it is due to a molecular friction probably, consequent upon that molecular motion which accompanies, if indeed it is not itself the current. This resistance, be it to water or to electricity, increases as the square of the current passing. The unit Ohm is then a conductor which presents so much of *this true resistance* as absorbs all the energy of a unit current produced by unit force. Hence, the Volt, the Ohm, and the Veber are simply different relations of, or different expressions for, *the same amount of energy*. Therefore, in multiplying them together, or dividing one by the other, as in Ohm's formulæ, we are not multiplying or dividing different concrete entities, which is really an impossibility, but simply working out an ordinary arithmetical calculation.

The energy put in the form of a Volt of electromotive force acting through a conductor of 1 Ohm develops 1 Veber of current *in that conductor*, and converts the whole of the energy into heat. This must be clearly realised. Under these conditions there is no development of what is called electrical action or electricity. The current can do nothing besides heating the conductor. If any external work is done, such as developing magnetism, the conditions are altered, the current is lowered just as if an additional resistance were inserted in the circuit. In fact *the work is an extra resistance*, and if it is valued in foot-pounds, or other unit of work, it can be expressed either as Ohms of resistance or as Volts of electromotive force, either of which may be the true expression according to circumstances.

I must now return to a statement just made that the Volt, Ohm and Veber are the same quantities of energy, which will no doubt take by surprise almost every one, because the volt is 10,000 absolute units, the Ohm, 10,000,000, and the Veber ·01, and the absolute unit is ·000,737,335lb. To explain this curious result of mathematical mystification I must use the table, p. 217, of my "Electricity: its Theory, Sources, and Applications," showing the convertible values of various units.

The Volt, as I have fully shown in that work, is a force derivable from chemical action in such manner that 4,073ft.-lb., maintains it under unit conditions for 0,338 seconds, that is to say, 4,073 ÷ 0,338 = ·737,335ft.-lb. per second. The energy of a Veber is ·01² × 10,000,000 = 1,000, and 1,000 absolute units = ·737,335ft.-lb. The heat developed in 1 Ohm by 1 Veber current is by experiment, calory ·21,665 which, converted by the mechanical equivalent of heat, is ·737,335ft.-lb. Q. E. D.

Hence we learn that the simple ratio of the elements of Ohm's formula $\frac{E}{R} = C$ furnishes us correct results because (1) each of

Electricity in Air.

RECENT experiments of M. R. Nahrwold tend to demonstrate that it is the dust in the air, and not the air itself, which becomes electrified. When air is sifted of dust by means of glycerine, it takes only a very feeble charge. M. Nahrwold also remarked that positive electricity discharges itself more readily in air than negative, a result contrary to those of Wiedeman and Ruhlmann, and we think also of Thomson. During the electric discharge, when viewed by the light of the mechanical theory of gases, would seem to show that the discharge, besides increasing the vis viva of the moving molecules, also increases the vis viva of the oscillatory motion of the ether envelopes. Different spectra got from different points in the width of the gaseous tube are therefore not to be referred only to the different temperatures of the gas, but to the amounts of electricity of which the passage causes the oscillation of these ether envelopes. Engineer July 1879

BY means of the formula given by Mr. D. G. FitzGerald in the *Electrician* for August 24th, 1878, it may be calculated that 1 lb. of zinc consumed in a Grove's cell—taking 1·80 volts as the average electro-motive force—would do 1,332,840 foot-pounds of work, and that 1 lb. consumed in a Daniell's cell—taking 1·09 volt as the electro-motive force—would do 1,170,500 foot-pounds, assuming the whole of the heat produced to be utilised in both cases. But, even theoretically, we cannot assume that more than half this heat would take the form of work. It has been found that 1 lb. of hydrogen combining with its equivalent of oxygen is capable of raising 51,146 lb. of water 1 deg. Fah.; 1 lb. of carbon, 14,500 lb. of water; 1 lb. of phosphorus, 11,900 lb. of water; and 1 lb. of sulphur, 2800 lb. of water. One grain of zinc was found to raise only 8 lb. 1 ft. high by means of an electro-magnetic machine. One grain of coal in the furnace of a Cornish engine will raise 143 lb. through the same distance.

Engineer July 1879

A PAPER, "On the Electric Dilatation of the Armatures of Leyden Jars," by M. Duter, was recently read before the Academie des Sciences. He finds the law verified, which is expressed by the equation $u = \frac{K V^2}{e}$, where u is the increase of volume of the jar, e its thickness, V the difference of potential of its armatures, and K a coefficient characteristic of the apparatus. He considers that electric pressure is not the cause of the phenomenon, but that there is here a new phenomenon of electricity. On the same subject, a paper was read by M. Righi. He distinguishes instantaneous dilatation, due chiefly to polarisation of the glass, from persistent dilatation, not before observed, and due to development of heat; and he thinks it probable that at the same time the polarisation, and perhaps also the attraction between the armatures, produce in the glass a diminution of thickness.

THE following method of constructing a voltaic couple or a home-made Daniell cell may be of interest to the student:—Select a small round earthenware jar, such as is used for keeping preserves, and having lined the bottom with gutta-percha, or some suitable cement, to the depth of 1in., fix upright in this a rod of zinc, of equal height with the jar, to which a length of copper wire has been attached by passing it through a hole drilled in the upper part of the zinc rod, or by soldering. Make a cylinder of pipeclay, or other porous clay, larger than the zinc rod, and having dried it, make it hot in the fire by degrees, till it attains a red heat. Let this cylinder cool gently, and when cold place it in the jar round the centre rod encircling it at a little distance. By moderately heating the end of the cylinder it will, when placed on the gutta-percha, make a groove which will fix the tube, and prevent infiltration of the fluids. Line the inside of the jar with a plate of thin copper bent into a cylindrical form and having a few holes punched in it, through which may be threaded the extremity of another length of copper wire. On the top of this cylinder place a flat ring of copper pierced with holes, and nearly, but not quite, touching the porous cylinder. This forms the battery. To charge it, the *Electrician* gives a saturated solution of sulphate of copper poured between the copper and the clay tube, and some crystals of the same salt are placed upon the perforated ring so as just to be in contact with the solution. The zinc compartment is then to be filled with a solution of sulphate of zinc, sal-ammoniac, or common salt.

Engineer July 18 1879

SEVERAL remarkable results have been recently obtained by Herr Kohlrausch in his researches on the electric conductivity of aqueous solutions, and especially on the influence of temperature on the conducting power of liquids, as given in the *Annalen der Physik.* Thus concentrated soda-lye, which, at a temperature of — 10 deg. conducts badly, acquires, under action of heat, a conducting power which increases regularly and with very great rapidity, so that at + 80 deg. the liquid conducts a hundred times better than at — 10 deg. A solution of bisulphate of potash behaves quite differently; its conducting power increases very slowly with the temperature, up to a temperature of 60 deg., at which there is a maximum. From this point the conductivity remains nearly constant, as the temperature is raised. Studying solutions of sulphate of soda, which are known to present at 33 deg. a remarkable peculiarity, due to the proportion, more or less, of water of crystallisation, Herr Kohlrausch found nothing peculiar in the conducting power. This, it is considered, seems to prove that water of crystallisation does not play any part in the conductivity of liquids for electricity. Engineer July 18 1879

Prof. ROWLAND of Baltimore made some observations on the new theory of terrestrial magnetism of Profs. Ayrton and Perry. He said the experiments on which the theory was founded had been attributed to Helmholtz, but they were entirely his own, he having gone to Berlin to make them. The new theory had occurred to himself. On making these experiments but he had rejected it because he found that the potential which the earth's surface would require to have would not only cause violent planetary disturbances, but by mutual repulsion drive objects off the earth. He had made also an experiment to see if absolute motion of electricity would cause magnetisation, but failed to get any effect from it. Then he resorted to calculation to find the magnetic effect of relative motion by rotation of a charged sphere of perfect magnetic permeability that is more magnetic than iron. He found that when the sphere was uniformly charged and rotating there would be a magnetic field in its interior; but instead of the result of Messrs. Ayrton and Perry that if the earth were charged to a potential of, he believed, 10^5 volts relatively to interplanetary space, the earth's magnetism would be what it is. He found the necessary charge to be 61×10^{15} volts. In the ordinary atmosphere this potential would produce a spark one million miles long, and discharge across to the moon. If the moon were electrified to the same degree the mutual repulsion would overcome the force of gravity between them. He therefore considered terrestrial magnetism to be still a mystery.

He had also thought that the aurora borealis might be explained by supposing the upper regions of the earth's atmosphere electrified; the winds carrying the upper strata towards the poles, electricity would condense there. This hypothesis is tenable still.

Prof. AYRTON said that whether or not the new theory of magnetism should be so rejected depended on whether or not Prof. Rowlands calculations or those of himself and Prof. Perry were wrong. It had been found by Sir William Thomson from experiments at Arran, that the earth was electrified with respect to the earth and that there is a difference of potential of 30 volts between earth and air for each foot of ascent. This gave 1360×10^{15} centimetre-gramme-second electrostatic units as the potential of the earth. The new theory required the potential to be 1011×10^{11} supposing the earth to be of solid iron, or about 14 times more—a wide margin.

Prof. ROWLAND said he had not seen the calculations of Profs. Ayrton and Perry yet, but he believed his results to be correct, as he had checked them.

Mr. BAILLEY exhibited a modification of Arago's experiment, in which a copper disc is caused to rotate continuously by changing the polarity of four electro-magnets underneath by a revolving commutator.

Mr. CONRAD COOKE exhibited a single voltaic element showing the internal current. This is done by forming the glass vessel containing the element into a helical tube between the poles, and hanging a galvanometer needle in the interior of the helix; the internal current deflects the needle.

ROTARY MAGNETIC POWER OF GASES.—M. Henri Becquerel finds that lighting gas, sulphide of carbon vapour, oxygen, and other gases shift the plane of polarisation of light under a powerful magnetic influence. Oxygen behaves like a highly magnetic body, and gives a negative rotation. M. Bichat also finds that the vapour of sulphide of carbon gives a decided result of this kind.

3676. "Magnets and armatures for producing motive power." H. E. NEWTON. Dated Sept. 17. 6d. A disc of metal or other material carrying a number of armatures is made to revolve either in a horizontal or vertical direction. A number of magnets equal to the number of armatures are arranged round it and each is attracted in succession by the permanent magnets. Each of the latter is temporarily neutralised after performing its attractive duty.

THE THERMAL AND GALVANOMETRIC LAWS OF THE ELECTRIC SPARK IN GASES.—To study this subject M. Villari has constructed a glass globe thickly coated with shellac, and furnished with four tubes, two vertical and two horizontal. These last are traversed by two brass electrodes, interiorly terminated by short wires of platinum or silver, with knobs of silver or platinum, and exteriorly terminated by brass balls. To the upper tubes is fitted a cock which allows different gases to be introduced. To the lower tube is fitted a long glass tube, of about 3 mm. diameter externally. This last tube is maintained vertical and plunged at its lower extremity in a glass which holds a mixture of glycerine and water. The apparatus is enclosed in an insulating box. This novel thermometer was placed in the circuit of a battery of eighteen Leyden jars. In the same circuit is placed also an electrometer jar, and a hand key. The battery was charged by the aid of a Holtz machine; the discharge produced a spark in the globe, and the heat resulting from it depressed the level of the glycerine in the vertical tube. With this apparatus (the electrometer serving to measure the quantity of electricity furnished by the battery), M. Villari finds that for nitrogen, oxygen, hydrogen, and carbonic acid (1) the heat developed in the gas by an electric spark is directly proportional to the quantity of electricity which produces the spark. With a galvanometer in circuit, M. Villari also found that (2) the deflections produced by the discharges of the jar were proportional to the quantities of condensed electricity. Further (3) the deflections produced by the discharge of condenser are constant and independent of the length of the spark produced in any part of the circuit; (4) the quantity of heat developed in a gas by the electric spark increases in proportion to its length, a result which implies that the temperature of the spark at its different points is independent of its length, and that the electric resistance of the gas is proportional to the thickness of the gaseous bed traversed by the discharge. (5) When the charge which produces the spark remains the same the quantity of heat developed by that spark is independent of the surface of the condenser. (6) The galvanometric deflections produced by the discharge of a condenser is independent of its surface. To sum up, the thermal and galvanometric deflections produced by spark or by discharge of condenser, are proportional to the quantity of electricity which produces them, and at the same time to the length of their active circuits, that is, the length of the spark or the length of the galvanometer wire.

Intrinsic Energy.

BY means of the formula given by Mr. D. G. FitzGerald in *The Electrician* for August 24, 1878, it may be calculated that 1 lb. of zinc consumed in a Grove's cell (taking 1·80 volts as the average E.M.F.) would do 1,332,840 foot-pounds of work, and that 1 pound consumed in a Daniell's cell (taking 1·09 volt the E.M.F.), would do 1,170,500 foot-pounds, assuming the whole of the heat produced to be utilised in both cases. But, even theoretically, we cannot assume that more than half this heat would take the form of work. It has been found that 1 lb. of hydrogen combining with its equivalent of oxygen is capable of raising 51,146 lb. of water, 1 deg. Fah.; 1 lb. of carbon, 14,500 lb. of water; 1 lb. of phosphorus, 11,900 lb. of water; and 1 lb. of sulphur, 2,800 lb. of water. One grain of zinc was found to raise only 8 lb. 1 foot high by means of an electro-magnetic machine. One grain of coal in the furnace of a Cornish engine will raise 143 lb. through the same distance.—*The Electrician.*

Nature July 24 1879

AT a recent meeting of the French Physical Society M. Bouty described the action of heat on metallised thermometers. The contraction produced at the moment of deposit of the metal is entirely compensated by the difference of the dilatations of the glass and the metallic envelope, at a temperature which is higher the greater the contraction, and the smaller the difference of the dilatations, but independent of the thickness of the deposit. Above this critical temperature traction takes the place of pressure on the bulb; ruptures presently occur at the surface of contact, and the result is permanent deformations, which produce a new displacement of zero. This latter effect is never produced when the critical temperature is not exceeded. A metallised thermometer may be used to measure temperatures, if it have been compared with a typical thermometer, from which it does not differ sensibly unless the metallic deposit be of considerable thickness. When sulphate of copper is electrolysed between two very sensitive thermometers, coated with copper superficially, the thermometer attached to the positive pole is found to be at a temperature superior, the negative thermometer at a temperature inferior, to that of the surrounding liquid. The same phenomenon is observed in electrolysing sulphate of zinc between two thermometers covered with zinc. M. Bouty recalled the fact that when two plates of zinc or of copper are kept at different temperatures in the corresponding sulphate, a current arises, and the warmer metal is the positive pole. There is between the production of these currents and the phenomena studied by M. Bouty a relation of reversibility similar to that which connects Peltier's phenomenon and ordinary thermo-electric currents.

Nature 7 1879

THE following is the prize theme given by the physico-mathematical class of the Royal Academy of Sciences of Berlin:—According to Faraday's theory of electrodynamics, as worked out mathematically by Prof. Clerk Maxwell, the generation and disappearance of dielectric polarisation in isolating media as well as in celestial space, are phenomena which possess the electrodynamical effect of electric currents, and which can be called forth like the latter by electrodynamical induction forces. The currents in question would, according to the theory, be equal in intensity to that one which charges the boundary surfaces of the conductors electrically. The Academy now demands that decisive experimental proofs be given for or against the existence of electrodynamical effects of nascent or disappearing di-electric polarisation, of the intensity supposed by Prof. Maxwell, or for or against the generating of di-electric polarisation in isolating media by means of electromotoric forces induced magnetically or electrodynamically. The term for sending in solutions of the theme ends on March 1, 1882.

The Sun as an Electric Focus.

Mining & Sci Press Aug 8 1879

The problem of the source whence the sun derives its heat and light is perhaps no nearer a practical solution now than it was a hundred years ago. It is true our knowledge of the constituent elements of the sun has increased, but that knowledge is only abstract. It has been contended that the sun is a burning mass, which, in the course of time, will "burn out," and leave the planets dependent upon it, uninhabited—dead. All of the combustible elements of this earth are said to be stowed-away sunbeams. The coal so largely used as a steam generator and for economical purposes, a product of the sun. Concentrated sunbeams, the hidden heat of which has been brought forth by the industry and genius of man for purposes of comfort and utility. Some writers have declared the sun to be pure fire, not fed by any supply, while others declare it to be the rendezvous of comets, the absorber of dead planets. Prof. Proctor estimates that in each second of time the sun distributes as much heat as would be produced by the consumption of eleven thousand eight hundred millions of millions of tons of coal. He further estimates that if the sun consisted entirely of coal, burning at this rate, it would burn out in less than 5,000 years.

If the sun derives its combustion from material within itself, it would seem as if there would be some diminution, and since Herschel looked at the orb and calculated its conflagration, such an enormous waste of gases would surely have been noticed by succeeding astronomers whose calculations are quite exact. But the light and heat of the sun is not on the wane.

The latest theory is that the sun is an emitter and receiver of electricity at one and the same time. It is contended that there is a mighty outpour of magnetic currents from the north and south poles of our planet, and that these currents meet and form a complete circuit, the sun being the point of meeting, as it is with the earth, so, also with all the other planets, only the outpour is greater, or less, according to size. Focality produces luminousness, and the currents are sent back to the planets and their satellites in proportion to their respective wants. Scientifically put, the new theory is that the planetary system is a vast magnetic-electric machine, or "generator," the planets being permanent magnets, which, while in motion, generate electricity enough for their own light and heat, with some to spare, the sun is the carbon point" where all these currents meet and become luminous. Thus, the sun, instead of depending on the combustion of coal, meteors or other fuel or friction, or "contraction" of its own surface, which would soon leave us in darkness, is dependent upon the electricity generated by the planetary system for its light and heat. This disposes of the non-eternity of the sun as a light-bringer to planets, and buries for an indefinite time Proctor's melancholy theory that the earth will breathe its last and give up the ghost as a life-producing and life-bearing body at a day somewhat too early for happy contemplation. It gives a possible solution of another vexed question, the origin of the aurora borealis, by assuming that when the electric currents are interfered with by meteoric or other bodies, the back-flow produces that splendid phenomenon. Altogether, the theory is worthy the attention of astronomers, who are as much in the dark about the sun's heat and light as unscientific persons.

Galvanic Dilatation.

In order to test Edlund's hypothesis that the passage of a galvanic current produces a mechanical elongation, M. Blondlot has contrived a delicate experiment. He takes a strip of copper, thoroughly annealed, which he bends into a kind of quadrangular spiral, fastened at its upper end and carrying at its lower extremity a shaft which plunges into mercury. When a current is passed through the spiral, all the angles should vary if there is any dilatation, and as all the variations are cumulative the terminal stalk should turn through an angle which could be easily measured by Poggendorff's method. An elongation of ·00000025 could be readily detected in this way, but as he found none, Blondlot concludes that the hypothesis is incorrect.—*La Nature.*

THE ELECTROMOTIVE FORCE OF MERCURY ALLOYS.—Mr. Hockin and Mr. Herbert A. Taylor have been engaged in a long series of experiments suggested by the curious, but well-known fact, that the amalgamation of a zinc plate generally renders the zinc more electro-positive than it was before amalgamation, while at the same time it protects the plate to a great extent from the action of dilute sulphuric acid. Their results show that potassium, sodium, cadmium, tin, and copper, are rendered more electro-negative by amalgamation. Lead and the other electro-negative metals are little altered. Iron and zinc are rendered distinctly more electro-positive in dilute sulphuric acid. In zinc sulphate zinc is not altered by amalgamation. The authors conclude that, within narrow limits, mercury alloyed with any number of metals takes the place in the scale of electromotive force of the most electro-positive metal that it may contain, if the amount of the electro-positive metal present is not less than about $\frac{1}{10000}$th in weight of the mercury. This seems explained by the facility with which a mercury surface becomes polarised, and the tenacity with which it retains the hydrogen. Also, if any zinc or other impurity exists on a portion of the surface of a mass of mercury exposed to an electrolyte, the whole service will fall to the potential of the zinc or other the most electro-positive impurity present. These laborious and important experiments of Messrs. Hockin and Taylor, are fully published in an original communication in the last number of the Journal of the Society of Telegraph Engineers.

Journ of Tel Aug 1 1879

TRANSFORMATION OF ENERGY.*

THE subject I propose to bring before your notice this evening is one to the development of which we owe the great strides which science has taken during the last half century. Though peculiarly physical, the modern doctrine of energy has an important bearing upon all branches of science, and it is well that those whose professional duties touch in any way upon any of these branches of science should have clear notions of what is really meant by energy. Philosophers are wont to speak of matter and mind as if they were only things which could be reasonably assumed to exist in the universe. We believe in the existence of matter because it affects our senses; but the great argument in favor of the objective existence of matter is its indestructibility—that is, the impossibility as far as our experience goes, of destroying matter or of creating matter. We can only shape matter, transfer or transform matter, but never has matter by pure physical means been called into existence. Now, in nature there is another something far subtler than matter, but possessing this same property of indestructibility,—a something, too, which can be traced in its actions in the material universe, and this something which we call energy, has as real and objective an existence as matter itself. The energy of a material system is usually defined as the capacity the system possesses for doing work. For example, in lifting a stone I do work against its weight, and the energy required to do that work was originally stored up in my muscle. The work I do is measured by the product of the force overcome into the distance through which it is overcome—i. e., by the product of the weight of the stone into the height through which it is raised. Say I raise a pound weight twenty feet, then I perform twenty foot pounds of work. In raising the stone I have suffered a certain fatigue, I have lost energy, but this energy, though lost to me, is not lost to the world, it is stored up in the raised weight which has now, because of its position above the earth's surface, a certain capacity for doing work. This energy of position in the mass is measured by the amount of work which I originally performed on it—namely 20 foot pounds; but if the mass be permitted to descend it, in its turn, will lose this stored up energy which will become transformed more and more into energy of motion as the mass, descending, gains in velocity. At the instant the mass touches the earth, the stored up 20 foot pounds of energy will be wholly transformed into energy of motion, which the mass still possesses. After the impact, however, the mass is brought to rest; it has been unable to overcome the resistance offered to its motion by the earth's surface; it has lost its energy, but this energy reappears in the heat and sound which are developed at the instant of impact. I have thus traced a certain portion of my muscular energy through a variety of transformations which ultimately end in the generation of heat. Throughout it all, however, the quantity of energy has been unaltered. Illustrations might be multiplied indefinitely. To-night I shall confine myself to electrical illustrations.

Let us consider a galvanic battery as our source of energy, and let us follow the transformations of part of this energy as exemplified in well known electrical experiments. The energy of the galvanic current is derived in the first place from the combustion of the zinc in the Bunsen cells which form the battery, and this combustion depends upon chemical action, which is simply a transformation of potential energy of molecular distribution. Into this we cannot enter at present, but pass on to the consideration of the electric current and the various ways in which it may be employed to do work. A current flowing along any conductor experiences a certain resistance, to overcome which it does work, and the energy which it so loses is transformed into heat. By passing the current through a thin iron wire, the heat generated is sufficient to make the wire glow till it melts. This process is familiar as a method by which mines are frequently blasted. Electrolysis or decomposition of a liquid (such as dilute acid) by the passage of a current affords another striking example. Here the energy of the current is expended in pulling the molecules asunder so as to separate them into their constituents. The hydrogen and oxygen into which acidulated water is decomposed may be collected in a vessel and exploded, when the sudden expansion of the water vapor produced by the combustion of the hydrogen in the oxygen causes a violent disturbance in the air, which is evidenced as sound. In this form we partly recover the energy which the current originally lost in effecting the decomposition. The discovery by Oersted, in 1820, of the motion of a magnet by a current flowing near and parallel to it, supplied the link which was wanting between electrical and magnetic phenomena. An electric current is as much the seat of magnetic action as a magnet is, and by suitable means the energy of the current may be transformed into the energy of magnetism. Wherever a current is flowing, there, of necessity, is a magnetic field; and if any system is acted upon energetically when placed in this field, as is the case with a magnet or a piece of iron, the current loses a certain part of its energy, which is first transformed into energy of motion, ultimately, as in all transformations, taking the form of heat. Thus, by passing a current through a wire coiled round a soft iron bar, the iron acts for the time as a magnet, and, indeed, all the phenomena of magnetism can be produced by means of helices or spirals of conducting wire. But not only does a current affect a magnet in its vicinity, but a magnet moving in the vicinity of a coil generates a current in the coil. More generally, if a magnet and conductor are in relative motion, currents are induced in the conductor, which, by the attraction or repulsion upon the magnet, tend to stop the relative motion. This is the explanation of the damping effect which a conductor, set below a vibrating magnet, has upon the vibrations of the magnet, and of Arago's famous experiment in which a magnet placed upon a rotating horizontal copper disk is dragged round after the disk. All these are special cases of induction, the nature of which was first thoroughly studied by Faraday, and all are included under the following general proposition. When the magnetic field in which a conductor is set is in any way altered, currents are induced in the conductor, which by their magnetic action tend to resist the alteration. This alteration may be effected by moving a magnet near a conductor, or a conductor near a magnet, or by mutual motion of a current-traversed coil and conductor, or by altering the intensity of the current flowing in the vicinity of a conductor. Upon this principle depends the action of the various forms of magneto-electric machines which are now so much used in the production of the electric light, as well as of the Ruhmkorff's coil or inductorium, whose working, as affording interesting examples of transformations, we shall consider in great detail. The induction coil consists essentially of two coils, the thicker internal one being the primary, and the thinner, but longer external one, the secondary. Inside the interior of the inner or primary is a bundle of iron wires, terminated at its extremities by disks of soft iron. When a current is passed through the circuit, the iron core becomes an electro-magnet, attracts a small iron disk, which forms the extremity of one arm of a lever, whose other extremity is consequently displaced, and by its displacement breaks the primary circuit. The current accordingly ceases to flow, the soft iron core loses its magnetism, and the lever returns to its original position, thus completing the circuit, and permitting the current anew to flow. The same cycle of operations takes place again, and thus an automatic or self-governing arrangement is produced, by which the current is made and broken in rapid succession. But at each make and break of the primary an alteration of the magnetic field results, and alternating secondary currents, rendered the more intense by the presence of the iron core, are induced. By this means

* A lecture by Mr. Cargill G. Knott, D.Sc.

96

a rapid series of sparks is obtained between the terminals of the secondary coil. To overcome the great resistance which the air presents to the passage of the spark, the second current must do work, and the energy so lost reappears as light, heat, and sound, which are the invariable accompaniments of the spark. The beautiful combinations of colored and stratified lights produced by passing the currents through Geissler vacuum tubes illustrate the same principles, and in all these varied transformations of our original source of energy the grand conservation law holds without exception. Naturally, however, energy, in whatever form it may exist, tends to the ultimate form of heat, which cannot be prevented from diffusing gradually all round. But this diffusion diminishes its power of being transformed, diminishes its availability for doing work. Hence at every transformation energy becomes degraded, or, as it is commonly expressed, dissipated, that is to say, though its total quantity remains constant, its entropy or availability for doing work is diminished. Ultimately, then, unless the energy of the material universe is infinite, its entropy will become zero, and the universe be reduced to a lifeless, motionless, characterless mingling of matter at a uniform temperature.

(3122) Electricity as a Motive Power.—The motive power used for the plowing you refer to is not electricity, but steam; the electricity is only used to transmit the power of a stationary steam engine to those points of the field where the traction of the plow is to be applied, for which purpose flexible and movable conducting wires are far more available than rigid, fixed steam tubes or belts. The operation consists of the use of two or three dynamo-electric machines, such as we described on page 145 of our July number. One of them is placed in the building containing the steam engine, revolved by the same, and the electric current generated is conducted by isolated copper wires to the field where the plowing is to be performed, the wires are there connected with the other machines placed in the field; the electric current has here an inverse action—it makes these machines revolve, and this with a power which, if compared with that of the steam engine from which it originally is derived, shows no more loss than is incidental to any other method of transmission, and certainly less than would be the case if the transmission had to be effected to such distances, and under such continually variable circumstances, as the positions of the other machines in the field have continually to be shifted; one is placed at each side of the field in which the plow is to be moved, and they are started alternately to pull the plow in both directions in which it crosses and recrosses the field. These machines, of course, work by wire ropes wound on revolving drums, and are placed on wheels and gradually moved forward while furrow after furrow is being made. As hand-labor is somewhat scarce throughout all France, and water power plentiful in many localities, it is expected that this method of transmitting the latter has a great future before it. It has already been successfully introduced in beet-root sugar manufactories for hauling and unloading material, and has been found to be far better for plowing than the steam plow, which can by no means be considered a success, but rather the contrary, and this for various reasons—their great first cost, weight, difficulty in moving, managing in the field, their necessary water supply, etc.; while the dynamo-electric machine, having no boiler, requires no water, costs far less than a portable engine for a steam plow, and does not weigh one tenth as much as a steam engine of the same power. There is no doubt but that this new method of transmitting power has a great future before it, especially in those sections in this country where circumstances favor its application.

(3120) Electricity as a Motive Power.—Have you not always been teaching that it was absurd to attempt the use of electricity as a motive power, on account of the great expense of electric batteries as compared with steam generators? How is it then, that, as the papers report, plowing by electricity is now being introduced very successfully in France? Please explain.—One of Your Old Cooper Institute Students, New York City. Manufacturer & Builder Aug 1879

D'ÉLECTRICITÉ EN LUMIÈRE

DESIDERATA NUMÉRIQUES. — 1er ARTICLE.

La Lumière — Électrique

Rendements absolu et relatif des machines électriques en travail mécanique proprement dit dans le cas de sources de forces électromotrices déterminées ou indéterminées. — Transport du travail mécanique à distance. Aug 15 1879

Soit un circuit fermé quelconque comprenant les résistances successives R, R_1,... R_n... R_s respectivement animées par des forces électromotrices représentées en signe et en grandeur par les quantités E, E_1,... E_n... E_s. — Appelons I l'intensité commune de la circulation électrique qui s'établit dans le système.

Le travail de chacune des forces électromotrices sur le circuit total pendant l'unité de temps peut, en unités absolues et avec son signe, être représenté par chacun des produits correspondants EI, E_1I,... E_nI,... E_sI.

Le travail thermique rendu manifeste sur chacune des résistances par la circulation effective sera I^2R, I^2R_1,... I^2R_n... I^2R_s. — Les termes correspondants de ces deux séries peuvent être deux à deux très-différents les uns des autres, mais la somme des termes de l'une des séries est forcément et rigoureusement égale à la somme des termes de l'autre série.

Cela est vrai quelles que soient les relations de dépendance réciproque de ces quantités, et quelles que soient les causes génératrices des forces électromotrices.

Si nous réduisons l'équation qui exprime cette égalité à n'avoir que 3 termes dans chaque membre et si nous supposons que l'une des forces électromotrices soit nulle, désignant par r la résistance correspondante à cette force nulle, l'équation deviendra :

$$IE + IE_1 = I^2(R + R_1 + r)$$

Si E et E_1 sont de signes contraires et que nous dégagions les signes, la formule peut s'écrire :

$$IE - IE_1 = I^2(R + r + R_1) \text{ ou : } IE = IE_1 + I^2(R + r + R_1)$$

$$\text{ou } I E = : \frac{E - E_1}{R + r + R_1} E = \frac{E - E_1}{R + r + R_1} E_1 + \frac{(E - E_1)^2}{R + r + R_1} \quad (*)$$

Cette formule exprime précisément ce qui se passe dans le cas d'un moteur électrique de résistance R_1 actionné à distance correspondante à la moitié de la résistance d'un conducteur de résistance r le reliant à une source de force électromotrice E et de résistance R, lorsqu'un travail extérieur d'ordre mécanique développe intérieurement dans la résistance R_1 une force électromotrice E_1 de sens contraire à celui de E.

Le premier terme est le travail total dépensé par la source le deuxième terme le travail pris par le moteur, c'est-à-dire la raison d'être d'un tel arrangement, enfin le troisième terme est le travail thermique qui, dans ce genre d'applications, peut être considéré comme un travail perdu et nuisible. Ces trois expressions représentent des nombres d'unités absolues électro-mécaniques et doivent, bien entendu, être multipliées par les coefficients indiqués dans un de nos articles précédents pour exprimer des kilogrammètres ou des calories lorsque les forces électromotrices et les résistances sont comptées en volts et en ohms.

Le travail dépensé peut d'ailleurs être fourni par une source quelconque, pile ou machine électrique actionnée elle-même par une puissance mécanique. Il y a de nombreuses observations à faire sur ce sujet, tout d'actualité, puisque l'attention publique s'est enfin fixée sur la belle solution, par l'électricité, du transport du travail mécanique à distance, solution à laquelle l'avenir appartient sans aucun doute.

Si dans la formule (*) nous faisons $E_1 = o$, tout le travail dépensé par la source sera employé thermiquement; au contraire, si E_1 augmente graduellement, le travail thermique perd de son importance et tend vers zéro pour $E_1 = E$.

En partant de la limite $E_1 = o$ correspondant à la seconde machine immobile, c'est-à-dire au moteur électrique stoppé, et, au moins pendant une certaine période des accroissements de la variable E_1, il y a donc accroissement du travail recueilli sur le moteur jusqu'à un maximum très-facile à déterminer algébriquement pour une valeur déterminée de E, lequel maximum est réalisé pour $E_1 = \frac{E}{2}$. Pour ce maximum il y a répartition égale du travail dépensé en travail thermique et en travail du moteur ou travail recueilli. Lorsque la variable dépasse $\frac{E}{2}$, le travail recueilli diminue en valeur absolue, mais augmente en valeur relative par rapport au travail dépensé et tend à l'égaler à la limite $E_1 = E$, limite à laquelle, d'ailleurs, chacun des trois travaux devient nul.

Notre but est de mettre le lecteur à même de suivre sans peine la trinité du régime des variations correspondantes des termes de cette simple et intéressante formule, et de généraliser les conclusions en y comprenant le cas où la source est une machine électrique extérieurement actionnée (E pouvant par suite être indéterminé).

Nous conviendrons des appellations suivantes :

Le rendement absolu sera la valeur absolue du travail mécanique recueilli par le moteur électrique pendant l'unité de temps.

Le rendement relatif sera le rapport du rendement absolu au travail dépensé par l'intermédiaire de la source pendant l'unité de temps.

$$\text{Par définition : rendement absolu} = K\frac{E_1(E - E_1)}{R + r + R_1}$$

$$\text{Travail thermique} = K\frac{(E - E_1)^2}{R + r + R_1}$$

$$\text{Travail total ou dépensé} = K\frac{E(E - E_1)}{R + r + R_1}$$

$$\text{Posons} \quad \frac{E_1}{E} = \frac{m}{n}$$

$$\text{Il vient : } \frac{\text{rendement absolu}}{\text{travail thermique}} = \frac{m}{n - m}$$

$$\frac{\text{Rendement absolu}}{\text{Travail dépensé}} \text{ ou rendement relatif} = \frac{m}{n}$$

$$\frac{\text{Travail dépensé}}{\text{Travail dépensé pour rendement absolu maximum}} = 2\left(1 - \frac{m}{n}\right)$$

97

$$\frac{\text{Rendement absolu}}{\text{Rendement absolu maximum}} = 4\frac{m}{n}\left(1 - \frac{m}{n}\right)$$

Nous pouvons donc construire le tableau suivant basé seulement sur des variations de rapports; ainsi nous ferons varier de 1 à 0 le rapport $\frac{m}{n}$ en passant par un certain nombre d'interpolations fractionnaires usuelles telles que $\frac{99}{100}$, $\frac{9}{10}$, $\frac{8}{9}$, $\frac{7}{8}$, $\frac{6}{7}$, $\frac{5}{6}$, $\frac{4}{5}$, $\frac{3}{4}$, $\frac{2}{3}$; $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$, $\frac{1}{6}$, $\frac{1}{7}$, $\frac{1}{8}$; $\frac{1}{9}$, $\frac{1}{10}$, $\frac{1}{100}$; les valeurs correspondantes de ces divers rapports deviennent celles posées au tableau ci-contre.

Il importe d'ailleurs de ne pas perdre de vue les distinctions et les liaisons qui existent entre les travaux d'ordre mécanique dont il est question dans la formule et le tableau, et le travail perdu soit en circulation électrique dans tout circuit autre que celui utilisé, soit en frottements; c'est-à-dire que, dans le cas de deux machines, il ne faut pas oublier que le travail total dépensé que nous considérons est le travail emprunté au moteur diminué du travail électrique qui peut être produit ailleurs que dans le fil de cette machine, si ladite machine électrique est plus ou moins imparfaite, et diminué aussi du travail absorbé par les frottements des coussinets de la première machine électrique. Tandis que la valeur considérée du travail recueilli sur la seconde machine comprend non-seulement le travail recueilli proprement dit, mais encore le travail absorbé par les frottements de l'arbre de cette seconde machine faisant fonction de moteur électrique.

Le travail du frottement absorbé dépend beaucoup, toutes choses égales d'ailleurs, du mode de relations de la machine électrique et de l'organe de transmission : ainsi, avec les transmissions dites par courroie, les raisons théoriques d'ordre électrique qui, ainsi que nous allons le voir, militent en faveur des grandes forces électromotrices de réaction E_1, se trouvent encore corroborées par les intérêts mécaniques qui demandent de grandes poulies, de grandes vitesses et de faibles tensions des courroies ou des câbles. On sait que dans cette sorte d'artifice mécanique réside tout le mérite des transmissions suisses et allemandes de travail moteur à grande distance qui réduisent autant que possible la traction sur les arbres et l'usure des coussinets. S'il s'agissait d'un travail en connexion directe avec l'arbre de la machine électrique, dans des conditions de symétrie d'efforts, il n'y aurait plus, de ce chef, le même intérêt à l'augmentation de la vitesse. Ce n'est du reste pas le moment d'insister davantage sur ce côté de la question.

Les formules et le tableau qui en est l'expression nous montrent à première vue que, pour un générateur donnant une force électromotrice déterminée : pile hydro-électrique Bunsen, pile thermo-électrique Clamond ou machine électrique d'induction dont le système magnétique serait, par exemple, constitué par des aimants permanents et dont le nombre de tours par unité de temps serait déterminé, on ne pourrait

(1) MM. Mascart et Angot l'appellent force d'induction. (*Journal de physique* de M. d'Almeida).

FORCE ÉLECTROMOTRICE DE RÉACTION (E) divisée par Force électromotrice de la source.	RENDEMENT ABSOLU divisé par Travail thermique.	RENDEMENT RELATIF.	TRAVAIL DÉPENSÉ divisé par Travail dépensé pour le rendement absolu maximum.	RENDEMENT ABSOLU divisé par Rendement absolu maximum.

augmenter le rendement relatif au delà de 1/2 qu'en diminuant la valeur du rendement absolu; mais nous voyons en même temps que, pour un même rendement relatif, nous pouvons augmenter le rendement absolu jusqu'à toute valeur déterminée, pourvu que nous puissions faire varier convenablement, dans le même sens, la force électromotrice mise en jeu par la source. C'est le cas dans lequel nous pouvons nous placer si la force électromotrice est indéterminée, par exemple, lorsque la première machine est actionnée de façon à pouvoir absorber constamment une puissance mécanique déterminée. Dans cette hypothèse, le rendement absolu peut donc, à la limite, égaler le travail dépensé.

Il n'existe entre ces deux faits rien de contradictoire, mais la question mérite quelque attention, car elle n'est généralement pas très-bien comprise.

Afin de procéder méthodiquement, considérons d'abord la simple donnée d'une source électrique quelconque à force électromotrice déterminée animant un circuit métallique. Cet unique générateur d'électricité est une pile hydro ou thermo-électrique ou une machine d'induction. Le circuit de la circulation électrique considérée comprend la résistance intérieure de la source et une résistance extérieure inanimée, c'est-à-dire une résistance exploitée qui n'est le siége d'aucune force électromotrice.

Il est certain que le maximum de travail recueilli sur le circuit extérieur (pour fixer les idées, en chaleur dans un calorimètre) est obtenu lorsque la résistance de ce circuit extérieur égale la résistance intérieure effective de l'électromoteur et ce maximum est le quart du travail qui représente ce que nous avons appelé l'énergie de l'électromoteur (travail de la force électromotrice déterminée animant un circuit dont la résistance est égale à la résistance intérieure de cet électromoteur), comme nous l'avons établi dans notre article du 15 juin 1879, page 53, du n° 3 du Journal universel d'électricité *la Lumière électrique*.

Si donc, dans de telles conditions, nous faisons varier de zéro à l'infini la résistance extérieure *r*, le travail recueilli extérieurement, ou ce qu'on pourrait appeler le rendement absolu thermique variera de zéro à zéro en passant par un maximum égal au quart de l'énergie pour une résistance extérieure *r* égale à R résistance intérieure, le travail total ou dépensé correspondant variera de l'énergie à zéro, c'est-à-dire ira constamment en diminuant entre ces deux limites en passant par une valeur égale à la moitié de l'énergie, valeur correspondant au rendement absolu maximum. Le rendement relatif variera de zéro à un, c'est-à-dire ira toujours en augmentant jusqu'à cette limite. Si maintenant nous supposons la force électromotrice indéterminée, et que nous appliquions à la machine électrique dont il s'agit une puissance mécanique déterminée, le nombre de tours devra être d'autant plus grand que la résistance totale extérieure et intérieure sera plus considérable et, pendant que la résistance extérieure variera de zéro à l'infini, le rendement absolu thermique varira de zéro à la valeur du travail fixe dépensé, et le rendement relatif correspondant variera de zéro à un.

Ainsi, à ce point de vue, laissant de côté les influences pratiques secondaires, il n'y aura donc pas d'empêchement théorique à réaliser un fonctionnement de machine magnéto-électrique permettant de recueillir extérieurement, en chaleur régénérée, la majeure partie du travail dépensé, les neuf dixièmes, par exemple, du résultat de la transformation du travail moteur en courant.

Sans doute, si l'on voulait appliquer une organisation de cette sorte, je suppose à la production de la lumière avec arc voltaïque (je prends l'arc comme type des dispositifs recueil-

lant la chaleur régénérée exposés à infliger des variations accidentelles considérables à la résistance extérieure, contact des charbons par exemple), la chose pourrait être dangereuse en ce sens que, lors d'une grande diminution de la résistance extérieure, le fil constituant la résistance intérieure de la machine serait aussitôt échauffé, pourrait même être brûlé, et cela d'autant plus sûrement que, dans la construction de la machine on aurait mieux réussi à la rendre apte à supporter juste la circulation électrique du régime prévu, avec un minimum de poids de métal conducteur.

Cependant, dans les cas où la résistance extérieure totale peut être maintenue sûrement entre des limites rapprochées, il n'y aura pas témérité à poursuivre simultanément toutes ces possibilités de maxima relatifs et spécifiques, et il est permis de supposer que ce pourra être précisément le cas pour les systèmes de production de lumière basés sur l'incandescence réalisée dans des conditions de constance suffisante des résistances exploitées.

Gressé.

(*A suivre.*)

SUR LES COURANTS D'AMPÈRE

RECHERCHES DE M. LE CAPITAINE DE VAISSEAU TRÈVES

L'importance des communications du capitaine de vaisseau Trèves, dans les deux dernières séances, suffirait amplement pour satisfaire les personnes curieuses des nouveautés scientifiques. Nous allons résumer les résultats obtenus par ce physicien éminent qui marche d'un pas sûr et rapide dans la voie entrouverte par Ampère.

On sait qu'Ampère s'est demandé si les courants moléculaires des aimants se créent de toutes pièces dans les corps magnétiques pendant l'aimantation, ou si la cause qui aimante ne fait que déterminer une circulation de courants préexistant dans les métaux à l'état naturel et il conclut dans le sein de la préexistence des courants dans les métaux magnétiques.

Les expériences ingénieuses de M. Trèves répondent parfaitement à cette conception d'Ampère, le courant *polarisateur*, circulant à travers les métaux magnétiques eux-mêmes, s'attaque directement à leur état physique; au lieu d'agir par influence.

Le savant marin prend deux hélices de même diamètre intérieur et de même section; l'une en cuivre; l'autre en fer doux, un même courant, circulant dans chacune d'elles; leur donne un pouvoir d'aimantation très différent. L'hélice en fer doux est près de cinq fois plus énergique que l'hélice en cuivre. Cela prouve que ce courant trouve, dans le métal magnétique un milieu d'action mieux préparé au phénomène de l'aimantation. Le courant de la pile, cause de l'aimantation, détermine la circulation et l'orientation des courants particuliers préexistants. Dans l'hélice en cuivre, au contraire, le courant de la pile, ne rencontrant pas sur sa route ces courants particulaires, ne donne qu'une aimantation relativement faible, provenant de l'action uniquement produite par la série de courants circulaires égaux et parallèles. Voici d'ailleurs une autre note de M. Trèves, portant avec elle une lumière encore plus éclatante sur ces questions délicates. On sait que tout courant rectiligne indéfini tend à diriger parallèlement à lui-même, un courant rectangulaire ou circulaire, mobile. Si donc, on prend un aimant droit ou un fer à cheval et si l'on y fait passer un courant énergique, d'une extrémité à l'autre, tous les courants d'Ampère, s'ils existent réellement, seront plus ou moins déviés de leur direction normale à l'axe et une notable partie de l'aimantation devra disparaître instantanément.

C'est précisément ce que l'on constate sur une boussole placée dans le prolongement du barreau, si l'on emploie un barreau de fer doux légèrement aciéré à la surface, et ne possédant qu'une faible aimantation relative. Quand le barreau est aimanté, les courants d'Ampère sont plus ou moins normaux à l'axe. Lorsque le courant de la pile passe d'une extrémité à l'autre, les courants d'Ampère pivotent, deviennent des ellipses, et l'aimantation s'affaiblit. Pour faire disparaître toute trace d'aimantation, on conserve l'un des pôles de la pile en contact avec l'une des extrémités du barreau et on le frictionne avec l'autre pôle de la pile. Au bout de quelques minutes, on détruit ainsi toute orientation des courants particuliers, et on rend le barreau à son état naturel. Dans cet état, si on continue à le frictionner en le faisant tourner sur lui-même, on voit le barreau reprendre successivement son aimantation, ainsi que le constate la boussole. Chaque friction polarise ou dépolarise, suivant le cas, les courants d'Ampère et les rend en quelque sorte visibles à tous.

Dans sa troisième note, M. Trève fait observer que rien n'égale la mobilité des courants d'Ampère, il est bon de redire l'énorme disproportion qui existe entre la force nécessaire pour aimanter un barreau d'acier et celle qu'il faut employer pour le désaimanter. Il faudra cinq éléments Bunsen, par exemple, pour aimanter à saturation un barreau d'acier. Pour dépolariser les courants d'Ampère, c'est-à-dire pour ramener le barreau à l'état naturel, il suffit de faire passer dans la bobine qui l'enveloppe le courant inverse d'un élément microscopique à eau légèrement acidulée. Il suffit de frapper quelques coups sur l'extrémité d'un barreau aimanté avec un corps même non-magnétique pour dépolariser les courants et lui faire perdre son aimantation. C'est un nouveau procédé de désaimantation, il suffirait d'un choc sur un électro-aimant plein ou tubulaire au moment où le courant cesse, pour diminuer la durée de sa désaimantation dans des proportions considérables, et remédier ainsi au magnétisme rémanent.

M. des Portes frappait un des aimants de téléphone suspendu par un fil avec une substance non-magnétique, et on en recueillait le bruit à l'autre téléphone. Ce résultat est la conséquence du *mouvement vibratoire* des courants particulaires d'Ampère, de ces courants dont l'existence n'est plus douteuse maintenant et qui pivotent si aisément sur leur axe.

Les nouvelles expériences de M. Trève nous paraissent si belles et si décisives, que nous n'hésitons pas à caractériser ces travaux, en appelant ce savant le fils d'Ampère, dans le domaine scientifique.

A. Boillot.

CAUSERIE ÉLECTRIQUE

Aug 18th 1879
La Lumière Electrique

Lorsqu'il y a quelques mois ce journal fut créé, dans un programme placé en tête du premier numéro, nous avons essayé de faire bien comprendre notre raison d'être et notre but. Nous y disions que dans la phase troublée que traverse en ce moment la science de l'électricité, nous pensions être utiles en offrant un centre d'études, un recueil de renseignements précis et scientifiquement contrôlés.

C'était dire que nous nous adressions aux personnes versées dans cette branche de la science, et que c'était surtout à ceux qui la connaissent et la travaillent que ce journal était destiné.

De ce côté, nous n'avons qu'à nous louer du résultat. La lacune que nous prétendions combler était sans doute bien réelle, et nous n'aurons pas été inutiles. Nous en avons pour preuve l'accueil que nous avons reçu, le nombre toujours croissant de nos abonnés, les témoignages qui nous parviennent, et dont nous remercions profondément nos lecteurs.

Mais en atteignant ce but, il devient tous les jours plus clair que nous en avons touché un autre; autour de nos abonnés techniques sont des personnes moins versées dans la science électrique, mais qui, néanmoins, s'y intéressent; elles nous ont fait l'honneur de chercher dans notre journal des renseignements propres à les tenir au courant.

D'autre part, le bruit qui s'élève aujourd'hui autour de ces importantes études éveille chez beaucoup de gens le désir d'en suivre le progrès sans être obligées à un travail d'instruction pour lequel le temps leur manque; elles ont demandé à notre publication le moyen de le faire.

Tout ce public n'a pas été sans éprouver parfois quelque difficulté à suivre nos travaux, dont l'allure un peu scientifique le gêne de temps en temps. On nous a plusieurs fois déjà témoigné le désir de trouver dans nos pages des articles où l'on éviterait l'emploi des termes techniques, et qui rendraient l'accès de la science plus aisé aux nombreuses personnes qu'elle attire.

Nous nous étions toujours efforcés d'atteindre, sans nous éloigner de la précision, la forme la plus claire; on paraît nous demander que nous poussions plus loin dans ce sens.

Il ne nous est pas permis d'hésiter devant un désir si bien d'accord du reste avec notre but, qui est, en facilitant les études, d'augmenter autant que cela nous sera possible le nombre de ceux qui aiment et cultivent la science électrique. Nous ne nous dissimulons point les difficultés. Exposer un fait scientifique à l'aide des termes et des procédés de la science, cela n'est pas toujours facile; cependant on doit y réussir, les moyens étant ceux qui conviennent au résultat cherché; mais l'exposer avec clarté et exactitude sans recourir à l'emploi de ces moyens, c'est un travail souvent plein de difficulté et de péril.

Nous l'essayerons néanmoins, puisque nos lecteurs le désirent. Dans chacun de nos numéros, on trouvera à l'avenir une Causerie électrique. Dans cet article, nous nous efforcerons de résumer et de rendre facile à suivre le mouvement de la science; soit que nous y donnions place à des faits non traités dans le journal, parce qu'ils sont connus des électriciens, soit que nous revenions sur les sujets traités ailleurs sous une forme plus sévère, afin de les présenter d'une façon plus accessible.

Il demeure bien entendu néanmoins que nous ne pouvons nous adresser à des personnes totalement étrangères à l'électricité; nous serons bien forcés de supposer quelques notions premières. Il faudra, par exemple, que notre lecteur nous comprenne lorsque nous parlerons d'une pile, d'un courant électrique; et ainsi de quelques termes absolument élémentaires; mais ces notions sont aujourd'hui si répandues qu'il est inutile d'insister sur ce point.

Ces articles, s'ils n'ont pas d'autre utilité, auront, au moins, nous l'espérons, pour résultat d'attirer l'attention quelquefois sur des sujets négligés et de montrer l'importance de découvertes qui seraient exposées à passer inaperçues.

Voyez, par exemple, le téléphone; à plusieurs reprises dans notre journal, d'importants articles ont signalé et décrit ses progrès; les autres publications scientifiques ont fréquemment occasion d'en parler, et néanmoins, il faut bien en convenir, cet appareil est, dans la masse, aussi peu connu que possible, et mal apprécié aussi bien comme découverte scientifique que comme importance pratique.

Beaucoup de personnes encore aujourd'hui confondent le téléphone électrique avec le téléphone à ficelle qui a tant amusé les enfants sur nos boulevards. Il a fallu pourtant une longue suite de travaux pour l'amener au point où il est. Pour ne signaler que les faits saillants, Page, en 1837, reconnaît qu'une tige de fer autour de laquelle passe un courant produit des sons lorsque ce courant est soumis à des interruptions rapidement répétées, et prouve que le son correspond exactement au nombre des interruptions; que si, par exemple, le courant est interrompu 435 fois par seconde, la tige autour de laquelle il passe donnera la note *la* qui correspond à 435 vibrations complètes. Il ouvre ainsi la voie aux recherches sur les vibrations moléculaires dues à l'électricité; phénomènes si curieux, si pleins de conséquences intéressantes.

Vers 1855, Léon Scott construit le phonautographe, un appareil qui enregistre la parole; il emploie pour cela une plaque de métal mince devant laquelle on parle et qui vibre sympathiquement avec la voix.

Les deux organes essentiels du téléphone sont alors trouvés: la plaque vibrante qui reproduit le son et le transmet, la tige vibrante qui le reçoit et le reproduit. Leur réunion a formé, vers 1870, le téléphone de Reiss, qui permettait de transmettre électriquement les sons musicaux à l'aide du courant d'une pile interrompu par une plaque vibrante.

De là à la parole articulée il y avait loin encore: le pas est fait par Graham Bell, dont le nom restera attaché à cette admirable invention. Il montra que pour reproduire la parole, il fallait lancer dans un fil conducteur, non pas des courants électriques interrompus, mais un courant modulé par la voix, qui s'infléchit et s'élève avec elle et exactement comme elle; un courant ondulatoire, suivant son expression. Parmi les moyens propres à obtenir ce résultat, il parvint à réaliser le plus simple, qui est de faire produire à la voix elle-même le courant électrique qui doit la transporter. Pour cela, reprenant la plaque vibrante de ses prédécesseurs, il la place devant un aimant; lorsque cette plaque remuée par le son s'éloigne ou se rapproche dans sa vibration, l'aimant en est troublé dans son magnétisme; ces variations peuvent être recueillies dans un fil qui l'entoure, sous forme de courants électriques; elles iront ainsi se reproduire à l'autre extrémité de ce conducteur, et animant une deuxième plaque vibrante d'un mouvement pareil à celui qu'a reçu la première, elles lui feront répéter les paroles que celle-ci a reçues.

Cela est si ingénieux et si simple à la fois, que bien des personnes à l'origine ne purent croire à ces merveilleux résultats. Ils sont certains cependant. Le téléphone de Gower, excellent perfectionnement de celui de Bell, les met aujourd'hui tout à fait en relief et les fait passer complètement dans la pratique.

N'est-il pas juste de dire qu'il y a là une découverte scientifique de premier ordre, et un appareil d'une extrême importance? On rencontre cependant beaucoup de personnes disposées à le traiter comme un jouet de médiocre valeur; c'est une idée absolument fausse et à laquelle il faut renoncer en toute hâte. C'est pourquoi il nous a paru utile d'y revenir.

Quand ce serait seulement pour les applications scientifiques, le téléphone resterait un instrument d'un grand intérêt. Il est l'organe essentiel du sonomètre que M. Hughes vient de construire et qui a été étudié dans le journal. Dans ce curieux appareil, M. Hughes envoie un bruit dans le téléphone, mais il l'envoie à la fois par deux courants de sens contraire, en sorte que s'ils sont exactement égaux, le bruit n'est pas entendu, les deux courants qui l'apportent se détruisant l'un par l'autre. L'appareil étant ainsi en équilibre, si l'un des deux courants est modifié en quoi que ce soit, le bruit sera entendu, les deux flux électriques cessant de se détruire. On peut, par exemple, approcher de chacun des deux courants un morceau de métal; si ces deux pièces ne sont pas de même nature, de même poids, de même structure, le bruit sera entendu et signalera la différence. On a pu trouver aussi un dix millième d'alliage, une différence inappréciable de densité; et M. Hughes a mis dans la main des expérimentateurs un des instruments de recherche les plus puissants et les plus délicats qu'on puisse imaginer.

La voie est à peine ouverte, et nous ne sommes qu'au commencement; les étonnantes expériences où M. Ader a montré qu'il n'est pas besoin d'un aimant ni d'une plaque pour reproduire la parole, qu'une tige de fer, une bobine de fil métallique peu serrée peuvent le faire, ont indiqué l'étendue immense que prendront ces recherches et leur extrême importance.

Elles resteront certainement un des grands faits scientifiques du siècle, et nous devions appeler sur ce point l'attention de tous nos lecteurs.

FRANK GÉRALDY.

Transparency of Metals.

With the aid of electricity films of several metals of such minute thickness as to allow the light to pass through them can be produced. An electric current is passed into a wire of one of the metals, that extends into a glass tube containing rarefied air or gases. The particles of metal that the electric current loosens from the wire are deposited on the sides of the tube and form a transparent film. The light that passed through gold was a very handsome green, silver produced blue, copper light green, platina bluish gray, zinc dark bluish gray, and iron brown.—*Chemiker Zeitung.*

General Science.

Electric Brevities.—Mr. Chandler Roberts has lately read an interesting paper before the Physical Society, upon his examination of the behavior of metals and their alloys with the aid of Prof. Hughes's induction balance. A complete induction balance has been installed at the Royal Mint, and Mr. Roberts is engaged in testing its capability of being employed in the assaying of the precious metals. He expresses himself well pleased with the results thus far obtained. As the paper is not suited for abridgement, we refer our readers for details to the *Telegraphic Journal* (August).——M. Lagrillo is reported to have devised a combination of telephone and phonograph of such arrangement that a telephone circuit transmitting speech shall impress it with sufficient force upon a phonograph of improved construction to repeat it if desired. The instrument is said to be experimentally successful, and it has been called the *telephonographe.*

Transformation of Sound into Light.—We glean from London *Nature* the following details of a new system of transforming sound into light, devised by M. Coulon, Conservator of the Industrial Museum of Rouen. Two Geissler tubes are put in quick rotation on an axis. The induction coil of the first is worked by an ordinary interrupter, and gives the deviation of a luminous cross. The interrupter of the second is replaced by a telephone. The figure presented by the second tube projects on the first one, which is colored by uranoxide glass, and exhibits the most rapid changes according to the height of the tone delivered in the telephone trumpet. The sensibility of the changes are said to be startling and most interesting.

The Relations Existing between Arc Resistance and Current Strength, and between current strength and illuminating power, have been studied by Professors Houston and Thomson; according to whom, within a certain range of conditions, the relations in question may be formulated as follows: 1. In arcs of equal lengths, the resistances are inversely proportional to the current strengths. 2. The illuminating power of an arc is approximately proportional to the current traversing it. 3. In arcs of equal length, the total energy given out is proportional to the current strength. For the details of this investigation our readers are referred to the (August) *Journal of the Franklin Institute.*

Engineering & Mining Jour

THE RELATION OF HEAT TO CURRENT STRENGTH.

[16010.]—It is generally stated in electrical textbooks, that the heat developed in a wire, through which a current is passing, is directly proportional to the square of the current strength. "Sigma" in his letters supports this, and if I understand him rightly, says, that it is because the energy thrown into the circuit is proportional to the square of the electromotive force: to both of these statements I object, and give my reasons for doing so as plainly as I can: for if right, plain speaking will only further the cause of right, while if wrong, plain speaking will only cause the more speedy correction of the error. If there be two voltaic cells having the same electromotive force, and each working separately through equal resistances, it is obvious that equal amounts of zinc are dissolved in each cell, and equal amounts of energy are thrown into each circuit, and of course the amounts of heat developed in one Ohm of each circuit will also be equal; and it would naturally be supposed that if both cells were placed in one circuit equal to one of those before mentioned, that the amount of heat developed in one Ohm of the resistance, would be twice as great as in either of the separate circuits, but instead it is found to be four times as great, although the current strength is only doubled. Now, according to the laws of electrolytic decomposition, it is plain that twice the quantity of zinc is dissolved in each cell, or in all, four times the amount of zinc in the one circuit, and consequently four times the energy (heat): this confirms the law which I object to. Taking another case, a battery is working in a circuit of 50 Ohms, and produces a current having a strength C; if that resistance is reduced to 25 Ohms, the current strength is 2 C; the amounts of heat developed in one Ohm in each case are to one another as 1 to 4; this is because, although the total amount of energy (heat) thrown into the circuit is twice as great, the one Ohm has twice the fractional value; that is, instead of being 1-50th of circuit, it is now 1-25th, and consequently receives four times the heat: this is the second confirmation of the law.

But now if two cells A and B are taken, having their electromotive forces as 1 to 2, and both working through equal resistances, it is plain the current strengths are also as 1 to 2; but it can be also proved that the amounts of zinc dissolved in each cell are also as 1 to 2; then the amounts of energy (heat) are also as 1 to 2, and any given portion of the circuit of one, say one Ohm, is receiving twice as much as an equal portion one Ohm of the other; while according to the objectionable law, the amounts of heat should have been as the squares of 2 and 1, that is as 4 is to 1.—Q. E. D. This is the simplest form of its incorrectness, and is quite sufficient to condemn the law as being universal. Perhaps "Sigma" will look over this, and point out the faultiness of my reasoning if it be faulty.

ELECTRO-MOTIVE FORCE, RESISTANCE AND CURRENT

[16050.]—I am inclined to think, with Mr. Moberly, 16011, p. 622, that small results will follow from our discussion; small, at all events, compared with the "energy" involved, considering that it has now taken him some seven columns to deliver his criticism, and there are "various points" reserved for further remarks; that my writings involved include a long chapter in my book, three articles, and a previous reply; considering further that each remark of mine is quite capable of calling forth a column of observations which would require three columns to reply to, I begin to feel that life is too short for so much of it to be spared upon an undertaking which would leave both of us much about where we began, and not prove deeply interesting or very instructive to many of our readers.

In fact, Mr. Moberly and I reproduce the instructive apologue of the two knights and the shield—with this difference, that I, at all events, am perfectly well aware that the subject of dispute has the two different sides. I say *the* subject in dispute, meaning the original one of the values of the electric units; most of the points raised in the letter under reply are either mistakes of Mr. Moberly as to scientific truths, or as to what I have said and meant. I will say something which may finish off the first. As I said when first replying, I had no opportunity of referring to my remarks under criticism. In fact the same observation which Mr. Moberly makes on the report of the B.A. committee applies to my description of the units. I gave the dimensional values of the various units at p. 149 of my book as the foundation of the system, showing what is the meaning of the units. But I was not writing for advanced electricians and people of high mathematical attainments; for them there are the works of Thomson and Tait, Clerk Maxwell, Cumming and others—works of high value, but hopelessly unintelligible to the people whose wishes I had in view (and with whom I sympathise inasmuch as it is extremely difficult to myself to get at their meaning, and then very imperfectly). My desire was to express the meaning, that is to say, the practical upshot, of what is buried in those pages of cabalistic-looking hieroglyphics. It happens that my work has in some sense succeeded beyond my expectations; it has gone among the class for whom I did not write it, and is scattering seeds of thought which I believe will produce considerable results; just the very results which Mr. Moberly has himself expressed in his last paragraph. But the shells in which those seeds of thoughts are enveloped are naturally offensive to the mathematical type of mind, and, of course, this gives rise to somewhat scornful criticism in some quarters, which I quite anticipated and am utterly indifferent to. But then it has also succeeded to my hopes, for I have received letters from all parts of the world, and from many leading electricians (foreign ones, of course, according to the old parable) expressing strong approval of the course I have taken. Returning, then, to the value of the units, I said, page 150, "From the foregoing (that is the $E = L^{\frac{3}{2}} T^{-2} M^{\frac{1}{2}}$ system) *it results* that the absolute unit is a single expression for all forms of energy; while the practical units in ordinary use have a known value, and may be converted into absolute units." I then gave the result I had arrived at as the physical meaning embodied in the system, in such manner as I had myself found useful. Mr. Moberly himself says that I have so worked it out as to "keep false theory (false, that is, from the technical mathematician's point of view) and true practice fairly well in agreement." Well, if my theory, or rather, my arrangement is in accord with practical needs, and simple of comprehension, that is what I aimed at; but I say, also, that it is true, because whatever the difference of expression, it is really based upon the absolute unit. But as my description is open to the doubt Mr. Moberly has raised, I will, while retaining my own simple system, point out, in the further edition which I shall have to prepare for some of these days, I suppose, more fully than I have done, the other aspects of the system.

I will now turn to a few of the other points of Mr. Moberly's letter. I do not feel at all disposed to enter into a dissertation upon abstract "force and energy," their distinctions and meanings; nor am I at all inclined to pass in silence the remark that "he admits the essential distinction between them": this would appear as though I had ever questioned that distinction. I think I may say that very few people have maintained that distinction more clearly than myself, or done much more to spread distinct ideas as to force and energy than myself. I will try presently to clear away some little indeterminateness which seems to exist thereon in Mr. Moberly's mind. But distinct as they are in science, it is hypercriticism to deny that there are many cases in which the terms are by no means very distinct; would it be wrong to speak of either the force or the energy of a blow? It is in definite science, and more especially in mathematical expressions and formulæ, that the distinction becomes clear and important. I do not think I ever miss the distinction where it has any real existence, but I noticed long ago a slip in my book p. 152, and will give here a correction I noted. "*Electro-motive Force.*—Force and Energy are generic terms for the sources of all the actions we are acquainted with, and modern science regards force as the *cause* of motion, and energy as *motion* in some form, when active, as the tendency to motion when in the latent or *potential* form." It is clear to me that anyone who cannot see the importance of the distinction between *quantity* of force and *degree* of force, has not quite fully mastered the distinction of force and energy. Force involves an abstract conception of the nature of tension or pressure, velocity, as in rate of vibration, and such-like *conditions isolated from quantity or mass*; thus we can speak of *degree* of temperature, or *quantity* of heat. *Quantity of temperature* would be absurd; *degree* of heat would mean nothing but temperature. Now, temperature measures the *force* of heat, the velocity of vibration, &c., but it has nothing to do with mass. But quantity of heat involves *energy*, and necessitates the consideration of mass. Furthermore, the distinction is perfectly clear and general that *force* is independent of mass, and *energy* connected to mass. Whenever mass has to be taken into account in considering force, or where area has to be taken into account, as in Mr. M.'s illustration of area of piston, it is because we are dealing with not a real force, but with energy, which we are, for various reasons, useful and necessary, expressing in terms of force; this I have explained often enough, by means of the same illustration of steam-pressure.

Mr. M., referring to my "laudable desire to explain what such expressions as $L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-2}$ really mean," seems not to understand what I really mean, or he would not suggest that I ought to have "traced out the way in which the originators of the expressions arrived at them." How on earth could I do so and be what I specially desire—comprehensible? Why, the originators themselves have written volumes on the subject, and no one can make head or tail of what they mean, except the few who, possessing a special order of mind, have spent years in training their minds to the comprehension of the subject. When David went out to fight Goliath, and the king fitted him out with his own armour, David put it off again, and said he had not proved it; in fact, he was more comfortable in his shirtsleeves, and felt himself master of his own simple weapons. Well, Mr. Moberly will not catch me encumbering myself with the mathematical paraphernalia which I make no pretence of understanding. They are no doubt very valuable, like Saul's sword and armour, in those trained to their use; but I prefer the natural side of science. When I spoke of giving the meaning of the symbols, I meant the physical natural truth, as it appeared to me, which those symbols convey or ought to convey. I should really like to know how many of our readers, for instance, comprehend the reasoning of Mr. Moberly's symbols, and how many (of course I mean of those really interested in the subject) simply passed them as if they were a Hebrew quotation.

I shall not attempt to follow up the rest of the letter. We might write pages upon pages about the commensurability of the foot as length, area and capacity, and be just where we are, each quite right in some points of view. The distinction and connection which I drew will still remain true. As to all the remarks in the third column, and the contrasts between some of my remarks and certain quotations from various writers, I fail to discover the meaning. The ideas attributed to me are often different from my own understanding of my words, and others seem to me misapprehensions of the authorities quoted. But they must just stand as they are. So far as they relate to my recent statement, that electro-motive force is really an expression based upon the square root of [illegible] involved in the circuit, I shall be quite ready to defend the proposition when it is definitely attacked upon the ground upon which I have placed it, the analogy between EMF and head of water. I refuse to defend it from all manner of general and side attacks which would necessitate ranging over the whole subjects of force and energy. In fact I shall really defend it by developing it from my own point when I have time and inclination. But a hint to Mr. M. He too agrees with me that electricity is energy charged upon material molecules.

Is it not a necessary sequence that the true expression for electrical agency must be in *terms of energy?* If for the purposes of mathematical analysis and formulæ we express electrical actions as the results of a force, *must not that force be an expression of the energy involved* in the electrical action? We all know that the energy expended in the circuit is in the ratio of the square of the EMF. Does it not follow naturally that the EMF is really the square root of the energy, the expenditure or supply of which is the true origin of the force? That view simply conveys the natural law that cause and effect are equal, or, to put it in symbols, $E = F$ and $F = E$, when E means energy, and F force. Why, some of these days I shall be told that I am enunciating as a new truth what everyone knew before (only they did not see what their knowledge covered). I trust Mr. M. will not treat this as he has my previous remark, that the units of force, LMT^{-2} and of energy, L^2MT^{-2}, are the same value; he says he agrees with me that "they are precisely the same value, all units are—" but they are very different things all the same. I do not think all units are the same value, and I do not understand what he means; but they are equal in value simply because one and the square of one are arithmetically the same value, and also because the natural law of equality of cause and effect requires that the unit force shall be simply an expression of the energy connected with it in its unit action or length.

Sigma

L'ACTION DE LA LUMIÈRE SUR LES PILES

La Correspondance Scientifique

M. Edm. Becquerel a déjà étudié avec soin et avec précision l'action de la lumière sur la force électro-motrice de certaines piles. M. H. Pellat, de son côté, vient d'entreprendre une série de recherches qui ne manquent pas d'intérêt, et que nous allons résumer en quelques lignes.

M. H. Pellat a préparé, comme étalon de force électro motrice, deux éléments Daniell. Les sulfates étaient contenus dans deux vases en verre concentriques et communiquaient par l'espace très étroit laissé entre le bouchon à l'émeri et le goulot du vase intérieur. Ces éléments, parfaitement transparents, ont été gardés pendant cinq mois; le zinc ne s'est pas altéré, mais le cuivre s'est recouvert d'une couche de vert de gris. Malgré cette altération, les éléments avaient conservé leur force électro-motrice primitive (1 volt. 15 pour l'un, 1 volt. 11 pour l'autre), quand la mesure était effectuée à l'ombre; mais l'exposition au soleil la *diminuait* d'une quantité qui allait jusqu'à 1/40 de sa valeur (0 volt. 029). La variation était très rapide et cessait dès qu'un écran interceptait les rayons solaires.

M. H. Pellat ne pense pas que ce phénomène soit dû à une élévation de température; l'immersion de la pile à 50° degré ne produisant pas d'effet bien sensible. En outre, un verre rouge, qui laissait passer la moitié de la radiation calorique solaire, produisait l'effet d'un écran opaque sur la pile. Par contre, une cuve contenant une solution étendue de bleu céleste, ne laissant passer que 1/7 de la radiation calorique, transmettait encore 1/5 des rayons efficaces.

On peut donc croire que ce sont les rayons les plus réfrangibles qui agissent.

Un élément Daniell, dont le cuivre est bien net, se montre tout à fait insensible à la lumière; mais il n'en est pas de même pour un Daniell dont le cuivre est altéré par oxydation ou par formation d'un sel à sa surface.

En concentrant, à l'aide d'une lentille, les rayons solaires sur les différentes parties de la pile, M. H. Pellat s'est assuré que le contact cuivre altéré et sulfate de cuivre est seul sensible à la lumière. L'action lumineuse rend le cuivre *moins positif*.

On obtient encore un élément Daniell sensible en prenant pour l'électrode positive un fil de cuivre oxydé dans la flamme d'un bec de Bunsen; mais, dans ce cas, l'élément *augmente* de force électro-motrice par l'action de la lumière. En mettant un pareil fil dans une solution de sulfate de cuivre et en complétant la pile par un fil de cuivre non oxydé, on constate effectivement que l'insolation rend le cuivre oxydé *plus positif*.

Tel est le résumé des instructives expériences de M. H. Pellat, expériences exécutées au laboratoire de recherches physiques de la Sorbonne. Nous sommes heureux d'en avoir fait connaître les résultats à nos lecteurs. Nous ajouterons que toutes ces mesures ont été effectuées par M. H. Pellat, en compensant la force électro-motrice de l'élément par une force variable à volonté par degrés continus et constamment connue, et que l'égalité était constatée au moyen de l'électromètre de M. Lippmann.

E. Venelle.

traine tous les vents de notre hémisphère. » Les faits sont plus complexes, et d'ailleurs, s'il en était ainsi, le maximum barométrique des Açores disparaîtrait de l'Atlantique pendant l'hiver : on sait aujourd'hui qu'il existe toute l'année.

THE INTERNAL CURRENT IN A VOLTAIC CELL.

On a Galvanometer for Demonstrating the Internal Current transmitted through the Liquid within a Voltaic Cell.[*]

By CONRAD W. COOKE, C.E., M. Inst., T.E.

It is of course well known that when the external circuit of a voltaic cell is closed a current of electricity is transmitted through that circuit, and at the same time a current of equal strength is transmitted through the liquid within the cell from one plate to the other. These two are in reality but portions of the same current, and are for convenience known as the external or internal currents respectively, to distinguish that portion of the main current which flows through the external conductor from that portion which is transmitted from plate to plate within the cell. The former of these is detected by its electro-magnetic and electro-chemical effects, producing deflections in galvanometers and electroscopes and sounds in telephonic instruments, and is utilised in all the applications of voltaic electricity.

As far as the author has been able to find out, there has not hitherto been any satisfactory means in the hands of the demonstrator of physics by which the existence of the internal current within a single cell can be made apparent. Faraday, in the course of his early researches, made the following experiment; he suspended a magnetic needle by a silk thread and lowered it into the liquid between the plates of one cell of a voltaic battery, so that its length should lie in a plane perpendicular to those of the plates, and he observed that when the needle was just below the surface of the liquid it was deflected the moment that the external current was closed. On lowering it still deeper (the current being maintained complete) its deflection gradually diminished as the depth of immersion was increased, until it reached a position about half the depth of the liquid, when it returned to zero, and after passing this depth it was again deflected, but this time in the opposite direction, its amount of deflection in either case increasing as its distance from the neutral or central point was increased. The cause of this phenomenon is obvious from the following considerations: If a wire carrying an electric current be held above and parallel to a magnetic needle, the latter, obeying Ampère's law, will be deflected with an angular displacement dependent upon the strength of the current and its distance from the needle; and if the same wire be held below the needle, the latter will be similarly deflected, but in the opposite direction. Now the flow of electricity through the liquid in a voltaic cell may, for the purpose of this explanation, be looked upon as made up of an infinite number of currents transmitted in a horizontal direction from one plate to the other; and when a magnetic needle is immersed just below the surface of the liquid, all these currents are flowing in one direction below it, and a corresponding deflection takes place; when, however, it is lowered deeper into the solution a certain number of currents are flowing below it tending to deflect it in one direction, and a certain number are flowing above it tending to deflect in the opposite direction; and its permanent deflection is due to the electromagnetic effects of the difference between the two. When these become equal, as they are when the needle is at the middle of its depth, their effects on the needle are balanced and neutralised, and no deflection takes place, and when that point is passed the currents above the needle are in excess of those below it, and a corresponding deflection in an opposite direction is given to the needle. This is an interesting experiment, but is very difficult to repeat on account of the feeble and unconcentrated nature of the electric currents above and below the needle, and the resistance offered to its motion by the liquid in which it is immersed.

Professor Hughes, by placing in the current of a battery an apparatus, such as a clock microphone, or a key by which an intermittent or undulatory character may be given to its current, and holding one side of a rectangular coil of wire in circuit with a Bell telephone over one of the cells of his three-cell battery, induced a secondary intermittent or undulatory current in the coil by that portion of the primary circuit transmitted through the cell, and a corresponding ticking was heard in the telephone.

In both these experiments, however, the effects observed must be attributed rather to the external current of the other cells than to the internal current of the cell under experiment; and the author is unaware that any successful attempt has hitherto been made to construct an instrument which shall utilise the whole of the internal current of a single voltaic cell for the production of electro-magnetic effects. While engaged in some experiments a few years ago it occurred to the author that if a voltaic cell were divided into two portions, having the zinc element in one portion and the positive element in the other, and the solution contained in the one portion were connected to that in the other by a tube filled with the same liquid, the tube being coiled round a magnetic needle, a deflection of the latter, due to the current within the cell being forced by the convolutions of the tube to circulate around the needle, would be produced when the two elements were connected together, and the apparatus shown on the diagram was constructed. This will be seen to consist of two glass tubes closed at their lower ends with perforated corks through which the ends of the coiled tube are inserted. Within the rectangular coil of the tube was suspended a magnetic needle, and the whole having been filled with diluted sulphuric acid, a plate of zinc was placed in one tube and a stick of carbon in the other. On making connexion between them by means of a wire, a slight deflection took place, but, owing to the feebleness of the current, the directive action of the earth's magnetism and the friction of the pivot, the instrument was not sensitive enough to be satisfactory, and the author therefore designed the instrument which is exhibited on the table, which consists of two glass test-tubes united together by a small tube about 2 ft. long, and convoluted into two circular coils after the manner of a Thomson's reflecting galvanometer. Within the coils is suspended an astatic system of magnetic needles of which the upper carries a light mirror by which its deflections may be made apparent by the movement of a spot of light on a screen. It may therefore in this respect be looked upon as a Thomson's reflecting galvanometer, coiled with liquid instead of with metallic wires. The elements are placed one in each of the little cells, and may be connected by a key; or, by placing a reflecting galvanometer in the external circuit, both currents may be simultaneously indicated on the screen and their independence or identity be demonstrated. The first instrument constructed by the author was made by connecting the two cells by means of a tube of india-rubber coiled round two cardboard cylinders, but through the kindness and unrivalled skill of his friend Mr. Gimingham, whose name is now inseparably connected with the splendid researches of Mr. Crookes, he was able to produce the instrument on the table, in which the tubes and coils are of glass, all in one piece, and it is a very beautiful specimen of accuracy of glass blowing. Below the base of the instrument is a fine slightly magnetised sewing needle, which can be rotated on a vertical axis through a small angle by means of a little lever, and by which the instrument may be adjusted to zero.

The author has been induced to bring the instrument before Section A of the British Association in the hope that it may be useful, not only for science teaching, but for aiding investigations connected with the physical action of the voltaic battery.

[*] Paper read before Section A of the British Association at Sheffield.

ELECTRICAL SCIENCE AT THE BRITISH ASSOCIATION.

Some New Instruments, recently constructed for the Continuation of Researches on Specific Inductive Capacity.

By J. E. H. GORDON, Asst. Sec. Brit. Assoc.

In this paper the author illustrated his observations by the exhibition of a miniature five-plate induction balance, similar in principle to the large balance shown at the Dublin meeting of the Association, but intended for the examination of crystals and other precious substances, which cannot be obtained in sufficiently large quantities for the balance; also a gauge for measuring the thickness of the dielectric plates to 1-10,000 inch, and a new form of quadrant electrometer for use with the small induction balance was shown. The capacity of the smaller plates of the little induction balance was so minute, that, when they were attached to the quadrants of the electrometer of ordinary construction (Elliott pattern), disturbances in them produced hardly any effect on the needle, on account of the much greater capacity of the quadrants of the electrometer. In order to construct an electrometer, whose quadrants should have very small capacity, and which should yet be very sensitive, Mr. Gordon had arranged the quadrants as pieces of a flat disc, only one inch in diameter, with the edges bent round them, so that the needle was acted on by both the upper and lower surfaces and the outside edge.

Mr. Gordon also exhibited a new rapid commutator, which was invented by Professor Cornu, of the Ecole Polytechnique, Paris. It could be used with either the large or small induction balance on the one hand, and with a Holtz machine or battery of 500 or more cells on the other. It reverses the electrification of the plates of the balance eighteen times per second, and between each reversal, short circuits, and puts to earth both poles of the induction balance, and both poles of the battery. By altering two screws it can be arranged to short circuit, and put to earth the poles of the induction balance only and to insulate the battery poles.

Secular Changes in the Specific Inductive Capacity of Glass.

By J. E. H. GORDON, Asst. Sec. Brit. Assoc.

The object of this paper was to describe the result of certain experiments made by the author by a method which has already been described before this section. The conclusion arrived at was

that in the course of a year and a half an actual change had taken place in the glasses, which was shown by a considerable real increase in their specific inductive capacities. To complete our knowledge of this new phenomenon, however, it was considered that a series of monthly observations was required extending over a period of several years. These experiments had some importance as regards Professor Clerk Maxwell's electro-magnetic theory of light. Mr. Gordon had recently suggested that it was quite possible that the relations between electric induction and light exists—namely, that they are disturbances of the same ether, but that there is some unknown disturbing cause affecting the electric induction. Possibly a clue to the nature of this disturbing cause might be found in the fact that the specific inductive capacities were affected by some of the changes which chemists assert are constantly occurring in glasses, but that these changes do not affect the refractive indices.

Electricity as a Motive Power.

By Prof. W. E. AYRTON.

Discourse delivered August 23rd, 1879, to the Working Men of England.

We hear on all sides new complaints regarding the stagnation of trade, the competition of foreign labour, and the difficulty found in disposing of English products to other countries. Various are the remedies suggested: on the one hand we are told that protection is the cure, because our trade is now almost entirely an import one, kept up by the export of English gold, and not, as it should be, by an exchange of English commodities for foreign ones. Consequently, there are some people who say that the only way to induce other nations to lower their prohibitive import duties, so as to stop this one-sided traffic, is to cause their own goods, now freely exported to Great Britain, to hang on their own hands, and that this can be done by the English temporarily also adopting protection. On the other hand we are assured that emigration is the panacea, and that it is the strikes which ruin the country.

But while the one side is maintaining, and the other side stoutly denying, that commercial depression can be cured by legislation, we are apt, far too apt, to forget that there exists a means by which, without lessening the wage of the workman, or the profit of the master, the cost of production can be diminished, prices lowered, and the failing trade of England resuscitated.

For is it only by burning coals that we can hammer our steel, turn our grindstones, work our lathes, and propel our trains? Coal is no doubt an extremely useful servant, but it is one that here in Yorkshire costs you five shillings a ton when you want to get power out of it, about twelve shillings a ton when used for melting metals and making gas, and about ten shillings a ton when you want it to warm your houses; therefore, as Mr. Bainbridge has been so kind as to ascertain for us that roughly in Sheffield alone about 500,000 tons are used annually for the first purpose; 750,000 tons for the second; 150,000 tons for the third; and 250,000 for the last of these objects, you see there is altogether an annual consumption in this town of about one million six hundred thousand tons, costing you therefore about £790,000 every year.

It is worth while, then, considering whether this consumption of coal can, even in a small degree, be replaced by any other source of power and heat.

For example, at Ottawa, in Canada, where exist perhaps the largest wood-cutting works in the world, the logs of wood come down from the mountains, are collected in the river, lifted and placed in position on the benches, sawn into planks, and stacked; but not a pound of coal is burnt. For merely by taking advantage of the fall of water which exists at the place, a man has merely to turn on a particular water tap to perform any particular operation.

For a stock of water on a hill is, to the people in the valley, what a coal mine is to a Sheffield manufacturer. As the water runs down the hill it can turn wheels, it can work machines just as can coal as it burns in the furnace of a steam engine. You all know the water wheels round Sheffield employed to work the grindstones and the tilting hammers. The high quality of the anvils coming from your Mousehole Forge, where water power is, or was, exclusively used, would be alone sufficient to keep water power permanently before you.

On Goat Island, between the Falls of Niagara, there is a paper works, the machinery of which is worked by the Falls. But what an infinitesimal portion of the energy of these Falls is used by that single paper mill. For, in addition to the gradual slope of the river, on account of which the water acquires considerable velocity, a hundred million tons of water come tumbling down every hour, through a vertical height of 150 feet. Now the power this represents is, of course, the same as would be required by perfect pumps to pump it back again. To raise a hundred million tons of water per hour, through 150 feet, requires the expenditure of nearly seventeen million horse-power; and this could only be produced, with even good steam engines having much above the average efficiency, burning, say 3 lbs. of coal per hour per horse-power, by an annual expenditure of about two hundred million tons of coal, which is about equal to the total consumption of coal throughout the whole world. And if it be remembered that there exist in the world other waterfalls besides Niagara, that we have also innumerable rapidly flowing rivers, the important fact well known to scientific men, but one which it is difficult to induce the world at large to grasp, stares us in the face—that we obtain, in a laborious way from the depths of the earth, the power we employ, and we let run to waste, every hour of our lives, many, many times as much as we use.

But it is not every manufactory that is situated directly over a stream, or even near a stream; and even when that is the case, as in Sheffield, you find streams are sometimes fickle, the tilting cannot be regulated with the same nicety as with a steam hammer—the natural order of things is reversed; water gives way to fire.

But were it possible, without water courses or cumbrous mechanism, to transport direct the energy of the mountain torrent, then machines in the very heart of a town could be worked as economically as those close to cataracts.

Again, even in a perfectly flat country, where waterfalls are unknown, the question of economic transmission of energy has no less interest. For you know that large steam engines can be worked much more economically than small ones. If, for example, I have a steam engine of many hundred horse-power, it can be worked by an expenditure of about two, or two-and-a-half, pounds of coal per horse power per hour, or, at the present price in Sheffield for steam coal, five shillings per ton, the best steam engines, if they be very large, can be worked at considerably less than one farthing

per hour. But if a man has a small grindstone requiring, say one horse-power to work it, and if he uses a small steam engine for this purpose, then instead of costing him less than twopence per day of eight hours' work, he will probably have to pay a shilling a day, in addition to the expense and trouble of getting up the steam; so that if he only uses the small steam engine occasionally, it will be hardly worth while going to the expense of having one at all. If, however, he could have transmitted to him, just at the time he might require it, a small amount of energy at, say, one halfpenny per hour per horse-power, which would be three or four times the actual cost of production of the horse-power with a very large steam engine, and if he could turn off the power like gas when he did not want it, so that one single hour's work with a one horse power grindstone cost really only one halfpenny, how many of the smaller workmen of Sheffield would be glad to avail themselves of such a facility.

But you will say in our large factories, in our huge cotton spinning mills in Manchester for example, we do use very big steam engines, and therefore this transmission of energy cannot produce any great gain there. Undoubtedly, these steam engines are fairly efficient, because they are so large; but what about the enormous mass of shafting used to connect this single engine with all the stories of the factory and with all the machines in each story? Why, the waste of power in friction in this shafting is so great that, in spite of the extreme inefficiency of small engines, it has been proposed as an economical measure, to replace the one large steam engine by many small ones, each driving two or three machines direct.

It might, at first sight, appear that the water already brought to our houses for drinking and for cleansing purposes, might be also used there for working small turbines or waterwheels, and I have heard this suggested as a possible means of utilising a natural source of power. But this is one of those delusions into which over sanguine people are liable to fall. For there are very few towns where the working pressure of water in the streets is more than able to raise it to a height of 100 feet.

Now 1 cubic foot of water weighs 62½ lbs.
therefore 1 " " " descending 1 ft. per minute
does approximately 1 foot pound of work per second.
That is—5½ cubic feet of water per minute } for every 100
Or— 330 " " " " hour } feet head
produce approximately 1 horse-power.

Some allowance must, however, be made, for the fact that our best turbines have at the most only an efficiency of 0·8, that is waste 20 per cent. of the power. We may, therefore, say that practically about

450 cubic feet of water per hour } for every 100 feet
Or—2,700 gallons " " " " } head
produce 1 horse-power.

But even in places like Sheffield, where the supply of water is large, the minimum cost in the town, when more than seventy millions of gallons are used annually, is not less than 6d. per 1,000 gallons. Consequently, with water at a pressure of 100 feet, it would cost about one shilling and fourpence per horse-power per hour.

In Sheffield, where the working pressure of the water in the lower parts of the town is also unusually high, being not less than 130 lbs. per square inch, or 300 feet head, it would be possible to produce work by small turbines at about fivepence per horse-power per hour, but this of course cannot be compared with less than one farthing per horse-power per hour, the cost of working very large, good, steam engines.

In our poverty and depression, our old servant, coal, is beginning to desert us, and to demand a higher price than we can give. Water, a yet older handmaid, refuses to work at all in our houses, except for extravagant payment. Where is it that we must turn for help? Where can we find the carrier that will, at a small cost, transport our motive power over long distances?

It is to electricity we must look for an answer to this question. It is to that fleet, subtle, messenger to whom we trust the carrying of our news that we must trust the carrying of our motive power.

To explain better what I mean:—When I turn the handle of this machine, my muscular energy is turned into electricity. This electricity is conveyed by the two wires before you to the small motor at the other side of the Hall, where it is converted back again into work. I put in work then here and I get it out again at a distance, without any shafting, straps, or pipes connecting the two places.

In exactly the same way, but on a much larger scale, Mr. Wilson will be so kind as to polish a knife with motive power supplied by Messrs. Walker and Hall, of Howard Street, and conveyed here electrically, by wires suspended to the spire of St. Paul's church, and crossing the streets as you see them in this diagram.

This other diagram shows you exactly how the machines in Howard Street, and these on this platform are electrically connected together.

Now these machines that are employed for this purpose depend on two important discoveries, the first, supposed to have been made by Romanosi, in 1802, who found that an electric current could produce mechanical motion; the second discovery, made by Faraday, in 1831, who, after the most patient investigation, was at length able to prove conclusively the result that he had long felt in his own mind must certainly be true, viz., that a magnet must somehow be able to produce an electric current. The first of these discoveries may be illustrated by the following simple experiment. Here we have a vertical copper wire, through which we can send an electric current either upwards or downwards. Behind the wire there is a magnet, suspended on a horizontal axis, so that it can turn in a vertical plane. The magnet is so arranged, that usually it stands upright; but if I send a current upwards, you observe the marked end turns to your left, while if I reverse the direction of the current, the marked end turns to your right, the magnet in both cases placing itself at right angles to the wire. Now, why does the magnet move when the current flows along the wire? Because the wire with the current in it produces in the space surrounding it the same effect that would be caused by the presence of a large magnet. For if I hold this other magnet in this position, perpendicular to the suspended magnet, you see the latter one turns with its marked end towards your left hand, as it did when the current ascended; and when I reverse the position of the big magnet, the smaller one puts itself in the same position as it did when the current descended. From this you would anticipate that since an electric current can act like a permanent steel magnet, in deflecting a suspended magnet, and since a steel magnet can make this piece of soft wire into a magnet by being put near it, that an electric current will also make a piece of iron into a magnet, a result first proved experimentally by Arago. When the electric current passes through this coil of wire, wound round this iron bar, the bar acquires the power to hold up masses of nails, but the moment the current ceases the iron, as you see, loses almost, but not *quite*, instantaneously, all its magnetic properties, and the nails fall to the ground. But since, by electricity, I am able to produce sufficient pulling force to hold up bits of iron, or, at will, cause this force to cease to act, then I must be able to do just as Newcomen did, when he made his so-called atmospheric engine.

For if we cause the attraction of this electro-magnet to pull a piece of iron, or armature as it is called, against the tension of a spring, and if, just when the iron is almost touching the electro-magnet, we interrupt the current, the spring will be able to pull the iron back again, and thus by repeating the action over and over again you see we can get an oscillating motion similar to that obtained in a single acting engine. And any oscillating motion you know can be turned into a rotatory motion by means of a crank and fly-wheel to make the crank pass the dead points. Now, the first man to make an oscillating electro-motor of this kind was a learned monk of Padua Salvator del Negro, in the year 1831. But an oscillating motion has many disadvantages, of which perhaps the most important in an electric engine is that the moving armature at the end of its stroke will be at a distance from the electro-magnet. Now the electro-magnetic attraction diminishes very rapidly as the distance increases, so that when the armature begins to approach the electro-magnet there will be very little force pulling it.

The Russian philosopher Jacobi explained this in 1834, and devised a rotatory engine in which the moving parts were not merely pieces of iron, but electro-magnets like the fixed ones. When the pole of one electro-magnet was approaching that of another due to the rotation of the apparatus, the currents were so arranged that there was attraction, but the moment the moving pole passed the fixed pole the electric current flowing round the former was reversed, so that there was attraction. An instrument such as Jacobi used may be seen working on the table, and like Jacobi's was originally intended to propel a boat. Here again I have a complete model boat driven by an electro-magnetic engine, with galvanic battery in the boat. A third electro-motor is working a Howe's sewing machine, while a fourth is a small engine running round on a pair of metal rails. This last would no doubt pass with the world as a mere toy, but the practical philosopher sees foreshadowed in it his dream of the future, just as Stephenson, in his "Puffing Billy," no doubt foresaw the express locomotive engine of the present day.

But after some time Jacobi abandoned his electro-motor, as the fuel cost far too much. Why then trouble you with considerations regarding electro-motors? Because we have since learnt why the old form was such an expensive producer of power, and what is the proper duty in which electro-motors should be employed.

Now, it was this very question:—Can an electric engine be made to work more economically than a steam engine that first attracted Joule of Manchester, in 1843, to commence that all-important investigation, which lasted for six years, the determination of the mechanical equivalent of heat.

Formerly, electric currents were almost entirely produced only by galvanic batteries, such as I have in my hand, in which zinc is burnt just as in the furnace of a steam engine coke is burnt. The amount of heat that could be got from burning a pound of zinc could be ascertained in the same way as the amount of heat produced by the burning of a pound of coal, but the fact that the latter was about seven times the former was of little value to the science of electro-motors, until Joule had proved that a certain quantity of heat is always equivalent to exactly the same quantity of work, no matter how the heat be produced; in fact, until Joule had arrived at that famous result which, although you know it well, will still bear repeating, that result which made the "Conservation of Energy" a law and not merely a speculation.

A quantity of water on a height, a heated body, a moving mass, two separated quantities of opposite kinds of electricity, an electric current, two chemicals which would combine if brought together, particles of attracting matter at a distance asunder, two planets in space, are examples of energy—each of the systems can be made to do work.

Now, experience shows that all these energies are convertible into heat, and that a certain quantity of each kind of energy is mechanically *exactly* equivalent to a certain quantity of any other. If a body, or if a system of bodies, possesses different kinds of energy, then as long as no energy leaves the system, or enters it from without, this sum is *perfectly constant*, no matter how one of these forms of energy may change into another form. Energy is in fact as indestructible as matter, and this law has one of its proofs in the long unsuccessful search for a perpetual motion.

Since, therefore, a pound of ordinary coal burning gives out seven times as much heat as the burning of a pound of zinc, we may say at once, that a steam engine would give seven times as much work as an electric engine for equal weights consumed, if in both cases all the heat could be turned into work; or, since zinc is about 24 times as dear as coal, that a steam engine would be about 150 times as economical as an electro-motor, worked by a battery.

But so far we have only considered the law of "Conservation of Energy." There is, however, another, and no less important, principle called the "Dissipation of Energy;" and this law tells us that although the energy of a system cannot by itself increase or diminish, yet our power to convert one form of energy into another is continually growing less, our stock of available energy is gradually failing. Our mountain lakes, our vast store of coal is practically useless until either the water is set in motion rolling down the hillside, or until the particles of the coal are set in rapid vibration as it slowly burns; energy of position, energy of chemical affinity, are of no use to the manufacturer until turned into kinetic energy or energy of motion. But from friction of various kinds, whenever energy exists in the kinetic form, some portion of it is being continually converted into heat. Whenever man or nature utilises energy it must be first turned into some kinetic form, and whatever be the aim of the special machinery employed some of this energy passes into heat. We cannot make even a clock go without regular winding up, although the only useful work done by the clock is to turn its hands at regular speeds; the earth's energy of rotation is now, like the moon's in past ages, gradually growing less, and is being converted into heat on account of tidal retardation; the earth, moon and sun, and all the planets are losing their energies of motion and relative positions, to be all ultimately turned into heat.

But at any rate it will be said there will still remain the heat, and since heat can be converted back into other forms of energy, we shall be none the worse off. But it must not be forgotten that whenever heat is produced some passes off by conduction through even our best non-conducting substances, and by radiation into space from even our best non-radiating surfaces; and this conducted and radiated heat, although it may impart some trifling warmth to unseen worlds, is for the greater part entirely lost to our universe. And even were it not so, even had we perfectly non-conducting coatings, and perfectly non-radiating surfaces,—had we, in fact, the most perfect heat engine that our study of the science of heat would lead us to believe theoretically possible, one with no friction, no loss of heat by conduction through the sides of our cylinders, and no radiation from their sur-

faces—still our power to convert heat into other forms of energy would be very limited. For if there are two bodies one hotter than the other we can employ an engine, like a steam engine, to convert part of the heat in the hotter one into some other form of energy; but the amount of heat converted, with even this ideal perfect engine, will, with such temperatures as are met with in practice, only be a fraction of what necessarily passes through the engine from the hot body to the cold, and warms up the latter; and as our whole power of conversion of heat into work depends on the difference of temperature, we lose it altogether when we have brought all parts of a system to the same temperature, no matter how high this temperature may be.

It is not, therefore, sufficient to say that the burning of a pound of coal produces seven times as much heat as the burning of a pound of zinc; but we must consider what fraction of the heat thus produced is converted into useful work in a heat and in an electric engine respectively.

As already mentioned, our most perfect steam engines can be made to produce one horse-power with the consumption of 2lbs. of coal per hour. Now, the burning of 2lbs. of coal will produce enough energy to raise 18,528,000 pounds one foot, or will produce 18,528,000 foot pounds of work. Now, one horse-power is equivalent to 1,980,000 foot pounds of work per hour, therefore, as regards the total energy in coal, even our best steam engines only utilize $\frac{1}{8}$ of it and waste $\frac{7}{8}$. But, as already mentioned, even a perfect engine cannot, with the ordinary temperature available, utilise the whole of the heat of the fuel. In fact, theory tells us that the efficiency of a perfect heat-engine, or the ratio of the work done on the maximum work obtainable from the consumption of the fuel, is equal to the ratio of number of degrees of temperature through which the steam is cooled in doing work to the highest temperature of our steam, when we take as our zero of temperature a point 460° below the ordinary zero of the Fahrenheit scale.

Now, in our best steam engines, the steam, when it begins to push the piston by expanding, has a temperature of about 300° F. and at the end of the stroke a temperature of 100° F. so that the efficiency of a perfect ideal engine working between these temperatures, is only about $\frac{1}{4}$, not so very much greater than that of best practical engines.

No great advance can be made then in a heat engine, except by making the temperature of the working substance, steam, gas, or whatever it may be, much higher. If, for example, we could raise the temperature of the working substance as high as, say, 3,000° F., the temperature of combustion, and could make it leave the engine without artificial cooling at the ordinary temperature of the air, which is, say, 60° F. then a perfect heat engine, under these conditions, would only waste about $\frac{1}{7}$ of the total energy; consequently assuming that we could, at these high temperatures, make a practical engine as good relatively to an ideal perfect engine, as we can at lower temperatures, then a practical engine would only waste $\frac{1}{6}$ of the total energy, or would have an efficiency of about 0·84.

But, with our present knowledge, to work with steam or gas at a temperature of 3000° F. is almost as ideal as an engine with no friction, and with no loss of heat by conduction and radiation. We are, therefore, led to the conviction that as it is solely by working with steam at very high temperatures, that the efficiency of steam engines can be seriously increased, it may be well to consider whether it is not possible to economically replace the steam engine with some other form of motor.

In order to estimate the efficiency of electric engines, we must consider the discovery made by Faraday, to which I have referred. We know that motion can produce electricity with the ordinary glass electrical machine, and that the electricity so produced can in its turn set up motion, as in the pith ball telegraph worked by Sir Francis Ronalds. We know that difference of temperature can produce an electric current, and the electric current can in its turn produce heat, or difference of temperature. Consequently Faraday felt sure that, since an electric current can, as you have seen, produce a magnet, a magnet must, in some way, be able to create an electric current. But his attempts were baffled time after time; failure, failure only was the result, yet buoyed up with hope, still persevering with that dogged earnestness which is the characteristic of an Englishman, he at length arrived at this all important discovery—to produce a current with a magnet it is no use placing the magnet this way or that way relatively to the coil, but you must have *motion* of the one relatively to the other. And this coil of wire before you is the very one made by Faraday's own hands, and which he used in investigating this problem. The results obtained with it were insignificant in magnitude, but they form the foundation of all the electric lighting of the present day and of the future electric transmission of power.

To enable you to better understand the discovery of "magneto-electric induction," I have here a coil of wire in which a magnet is suspended, and free to move in a vertical plane. Attached to the magnet is a pointer to enable you to detect any motion of the magnet. Those of you who are near will see the pointer itself, while those who are at the other end of the room will see it projected on to the screen as a huge vertical black bar. The exact construction of this instrument is also shown in the large diagram.

Now, we know from our previous experiments that this arrangement will detect whether an electric current is flowing through the wire and also which way it is flowing; in fact the instrument is in principle exactly the same as the one I previously used, only, as the wire goes many times round the magnet in this second instrument, it will detect a much weaker current. To the two ends of the wire forming the current-detector are attached the two ends of the wire forming this coil. The pointer of the detector is now vertical, indicating that no current is passing; but if I rapidly move this magnet towards the coil, the pointer deflects to the left, and then comes back again to the zero position, indicating that an instantaneous electric current was set up in one direction. Now, if I rapidly remove the magnet I have in my hand, you observe the pointer makes a swing towards the right, indicating an instantaneous electric current in the opposite direction. To be quite sure that the deflections you saw produced in the suspended magnet are the results of electric currents, and are not produced by the direct attraction of the large magnet I hold in my hand, on the suspended magnet, I make a break in the circuit of the wire so that electric currents cannot now flow; and you observe that the motions of the big magnet produce no effect whatever on the little one at this distance.

Now, we have seen that an electric current can do work, and the principle of the conservation of energy tells us that work cannot come out of nothing, therefore, my hand, in moving the magnet, must do as much work as is performed by the current. As this current is weak it would be a little difficult to measure, in a simple way, the work done by my hand; but if we take a machine for producing strong magneto-electric currents, a machine called the "magneto," or "dynamo-electric machine," then as long as the wire is incomplete so that no current can flow, you see it is quite easy for me to turn the handle, but the moment a small

piece of wire is inserted so that a current is induced, my hand is arrested—I can hardly turn the handle—I have to do work, hard work, in order to continue the motion of the machine, and that work has its equivalent in the electric current that flows, and in the heat which you see the current is producing in the piece of wire we inserted, and which has now become white hot.

But, perhaps you may say, although this is very interesting in connection with the mechanical production of electric currents, what has it to do with the comparison of steam engines with electro-motors, the object of which is not to produce currents, but work? The answer is, because every electro-motor, every instrument that is worked by an electric current, is also a magneto-electric machine, that is, can produce electric currents, and, in addition, always is producing electric currents when it is itself set in motion by one. For taking this simple form of electro-motor—where an iron armature is attracted by an electro magnet—this attraction arises from the fact that as soon as the current is started, the iron armature is first converted by induction into a magnet before it is attracted; consequently when it moves up to the electro magnet, we have the case of a magnet approaching a complete coil of wire, the result of which you now know is the production of an electric current. Now, this electric current must be in the opposite direction to the original current producing the motion, for otherwise the original current would be increased by the induced currents, therefore the armature would be pulled with more force, and the total work done by the original currents would be increased without any equivalent consumption of energy elsewhere. This induced current therefore, like all currents induced by the motion of magnets, relatively to coils of wire, *tends to stop the motion*, and must be taken into account, in calculating the efficiency of an electro-motor; in fact not only must be taken into account, but experiment shows us that it is this tendency of the electro-motor to send a back current that makes it an electro-motor at all.

This reverse current may be thus shown experimentally. I have here a battery sending a current through a Froment's electro-motor, which, as you see, can work either this pump, or this pile-driver. Now, the strength of the current, as measured by this galvanometer, is 40° when I hold the electro-motor at rest, so that it can do no work, and 30° when I allow the motor to move rapidly as you now see it doing.

When an electro-motor is worked by a *given* galvanic battery, then calculations lead us to the result that if we wish to produce the work *most economically* we must, by diminishing the load on the motor, allow its speed to increase until the reverse current it produces is only a little smaller than that sent by the battery; in fact, until the current circulating through the arrangement is very small, in which case the efficiency of the engine, or the ratio of the work it produces in a given time to the maximum work it could produce from the same consumption of material is nearly unity. If, on the other hand, we desire a *given* battery to cause the motor to do work *most quickly*, independently of the consumption of material, then calculation tells us that we ought to put such a load on the motor that its speed will send a reverse current equal to something like a half of the strength of the current the battery could send through the motor when at rest. In this case the efficiency is about $\frac{1}{2}$, or half the energy is wasted in heat.

The difference between these two considerations of maximum values must carefully be borne in mind, especially as it is usually the second—or how to obtain work *most quickly*—that has generally been taken into account, whereas, this evening, it is the other one—or how to transmit work *most economically*—that will specially engage our attention.

Now, let us consider that we work our motor in the most efficient way—that is very fast with a small load, and let us consider that by so doing the efficiency is so little short of unity that we may regard it as one, then since an electro-motor worked by a battery in which zinc is burnt is 150 times as dear as a steam engine for equal efficiencies, the best electro-motor worked by such a battery will be 33 times as dear as our best steam engines having an efficiency of $\frac{2}{9}$. We may, therefore, throw on one side at once all idea of electro-motors worked by ordinary batteries, even although the electro-motors be perfect. Now, this result is most important, since it shows not that an electro-motor as a machine is inefficient, but it tells us that attempting to drive it with a galvanic battery is the hopelessly inefficient part of the arrangement.

But if we turn to the question of using electro-motors for the transference of power, then there is no difficulty about burning zinc, and the high efficiency of such motors is all important.

For in the case of natural sources of power, such as waterfalls, we have merely to consider what amount of energy will be produced at the distant factory; will it be sufficient to repay the expense of putting up wires from the source to the factory, together with the cost of the two dynamo-electric machines, or will it be cheaper to put up and use a small steam engine having probably an efficiency of only $\frac{1}{12}$?

When the distance between the source and the motor is considerable, the cost of putting up the leading wires becomes important, and the question therefore arises, can two or more people use the same leading wires without increasing the thickness, or must the thickness of the wire be so much increased as to make the construction of two sets of leads as economical?

To this question I must beg your most careful attention, since the answer to it, which I hope I may be able to put it in the power of all of you to give, will decide whether the electric transmission of energy is a mere dreamer's fancy, or is likely to have a real commercial future.

In order to decide this let us consider what proportion of the power is lost in transmitting it by electricity and what is lost when water is used as the carrying agency. For convenience we will take the second question first.

Let w pounds of water flow per second out of a reservoir, along a pipe into a town, then if there was no friction whatever in the pipe, if the pipe were perfectly smooth so that the water could slip past the surface quite easily, then the work the water could do in the town would be

$$w\,H \text{ foot pounds;}$$

but experience shows that in reality this amount of work, when the pipe is straight, is diminished by at least

$$w \frac{4\,f\,l\,v^2}{d \times 64{\cdot}4}$$

where f is a number depending on the smoothness or roughness of the pipe, l the length, and d the diameter of the pipe in feet, and v the velocity of the water in feet per second with which the water flows through the pipe. The work, therefore, that the water can do in the town is only the difference between these two last quantities, or

$$w \left\{ H - \frac{4\,f\,l\,v^2}{d \times 64{\cdot}4} \right\}$$

and the loss goes to slightly heat the pipe and the water. This loss will, in reality, be even greater than

what I have mentioned, as there is a certain amount of friction where the water enters the pipe at the reservoir, and additional friction at every bend of the pipe.

Now *w* pounds of water per second flowing, may be enough to work one man's machine, but suppose we want to increase the work done, we must, if we cannot alter the reservoir, diminish the water pressure in the town, to allow the velocity of the water and the quantity flowing per second to become greater. Suppose we double *v* then *w* will also be doubled. Double the energy will, therefore, be taken out of the reservoir, but the power furnished in the town will not be twice as great as before, since it would only be twice as great if we could both double the current and keep the pressure in the town constant; the loss, too, of power in the pipe will now be eight times as great as before, so that if we go on supplying a town in this way with motive power, the loss of energy will soon become ruinous.

But there is another way in which theoretically we can increase the power conveyed to the town, and that is by increasing the pressure at the reservoir, as well as the pressure at the town. Suppose, for example, that we double the pressure at the reservoir and increase the pressure at the town sufficiently to keep the difference the same as before, then the velocity of flow and therefore the quantity discharged will remain just the same. The waste, therefore, will not be increased, the power absorbed at the reservoir is double what it was before, while the power given out at the town is more than double what it was before, since the pressure in the town will have to be more than doubled to keep the current constant.

Such an arrangement, as far as we have gone at present, would then be a good one, since if we can much increase the pressure at the reservoir, and use at the town turbines, or water engines, working at a high pressure, we shall be able to transport any amount of power with exceedingly little loss.

Is this then the solution of the problem to transfer power economically by water? Theoretically, yes; practically, no. For when we talk of increasing the pressure at the reservoir, how are we to do it?

We must use some kind of force pump, worked either by a steam engine, having a combined efficiency of perhaps $\frac{1}{10}$ at the most, or by a considerable quantity of the water at a low pressure working a turbine which drives the force pump. Now, the combined efficiency of the pump and turbine will not be more than $\frac{4}{5}$. Taking this latter as being the larger and that assuming at the town itself we have some sort of waternotor, having an efficiency of even as much as 0·8, then the combined efficiency of the whole arrangement cannot be more than 0·32.

(*To be continued.*)

ELECTROMOTIVE FORCE, RESISTANCE, AND CURRENT.

[1022.]—I am sorry to be obliged to take up so much space on this subject, but "Sigma's" replies are so unsatisfactory that I feel it to be necessary to do so. He persists in mixing up two things: the physical meaning of certain phenomena of electricity, and the mathematical processes employed in defining and measuring them. His "hard thinking," referred to by "Eclecticus," is well known to readers of this paper, and I have the greatest respect for his interpretations of electrical phenomena, so far as they are consistent with the mathematical theory. But, when the two clash, "Sigma" must pardon me if I insist that he is bound to show where the mathematical theory is wrong, or, if he cannot do that, then to conform his interpretation to it. Now, there are three principal points upon which "Sigma's" interpretations conflict with mathematical principles. The first is the distinction between force and energy, which, he says, consists in this: that force is independent of mass, while energy is dependent thereon. Avoiding semi-metaphysical discussions as to the intrinsic nature of force and energy, about which the wisest of us know very little, I merely ask "Sigma" whether his distinction is consistent with the fact that we measure force by the mass moved, and by the acceleration produced therein? May I also, in passing, suggest to him that the distinction between the two, whatever it consist in, is lost sight of not only in the passage on page 152 of his book, for which he has noted a correction, but also in the list which follows it, and in all the earlier part of Chapter VIII. Considering that "Sigma" was writing in a scientific periodical, and on a scientific subject, his remark that, though distinct in definite science, "it is hypercritical to deny that there are many cases in which the terms are by no means very distinct," is somewhat superfluous. I know perfectly well that the terms force and energy are popularly used as synonymous, but that does not make such use of them any the less wrong.

The second point on which "Sigma's" interpretation and the mathematical theory are at variance is the derivation of the Volt, Ohm, and Veber. In his book these are described as respectively 100,000, 10,000,000, and ·01 "absolute units"—a very vague description, which may be either right or wrong, according to what absolute units are meant. But in his recent articles he explained that he meant thereby the absolute unit of force, and when called upon to defend this description, he points to the table of dimensions of the various electric units given in his book, as showing what the units mean. Quite true, only the Volt, Ohm, and Veber are not mentioned there. All other authorities agree in stating that they are multiples of the absolute units of electromotive force, resistance, and current respectively; and these three units being measured in different ways, as shown by their dimensions, they are necessarily incommensurable with each other, and it follows that the Volt, Ohm, and Veber are also incommensurable (using that word in the usual sense). Now, "Sigma's" result is directly opposed to this, and I positively deny that any subject can have two aspects which contradict each other; one of the two *must* be wrong; but as "Sigma" chooses neither to defend his view nor to correct it, I must leave it to our readers to say which is wrong. But "Sigma" does not appear to realise that unless two things are measured in the same way, they cannot be of the same kind, nor can they bear any ratio whatever to each other. For when in my first letter I affirmed this of force and energy, giving as the reason that the dimensions of their units are different, "Sigma" asked whether this was so, and if so, why? I omitted accidentally to give the answer in my last letter, and will do so now. Will "Sigma" consider for a moment what would be the effect in our measurements of force and energy if we simply altered the value of one of the fundamental units which enter into the measurement of both? Take 10in. as the unit of length, instead of one metre, then the nominal value of what was unit force (LMT^{-2}), will now be 1-10th, but the nominal value of what was unit energy (L^2MT^{-2}) will now be 1-100th. Similarly with the units of electromotive force ($L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}$) and energy, if we take 100 grammes as the unit of mass instead of one gramme; then the nominal value of what was unit E.M.F. will now be 10, whereas the value of what was unit energy becomes 1-100th. A simple change, therefore, in one of the fundamental units common to both, changes what (according to "Sigma") are equalities into differences of value in the one case of ten, in the other of 1,000-fold. "Now, two things which are really equal to one another must necessarily be expressed by the same numerical quantity *whatever* system of units be adopted." This is a quotation from Prof. Tait's lecture on force, published in his "Recent Advances in Physical Science," and he goes on to say, with reference to a common error of confounding momentum with force that, "whatever be the system of units you employ, if you increase in any proportion the unit of time, the measure of a momentum is increased in that proportion simply, while that of a force is increased in the duplicate ratio. *The two things are therefore of quite dissimilar nature, and cannot lawfully be equated to one another under any circumstances whatever.*" Now, *mutato nomine*, this applies equally to force, electromotive force and energy, and is almost word for word what I said in my first letter, though I had not then read Prof. Tait's lecture. The argument appears to me absolutely conclusive, and "Sigma" must be capable of wriggling out of his skin if he can wriggle out of this!

The third point will take more time. The object of my quotations, as "Sigma" might have seen, was to show that authoritative definitions contradict his doctrine that energy varies as the square of force. Whether this was meant to apply to ordinary mechanical force or to E. M. F. only, matters not; both are equally wrong. If it were as he said, the term electromotive force would be an abuse of the word force, for, whatever be its kind, "force" is by its very nature a cause to which the effect produced must, *cæteris paribus*, be simply proportional, whereas here the cause would not be the E. M. F. simply, but its square. "Sigma's" words "cause and effect are equal, or, to put it in symbols, NE = F and F = E, where E means energy and F force," can bear no other meaning, unless indeed that effect varies as the square of cause, which would not only be contradictory but ridiculous. "Sigma" appears to have forgotten for the moment what he himself has said on p. 210 of his book: "the real fact is that II (the energy of a current) varies not as the square but in the direct ratio of the current, that is of the number of molecular actions in a given time, but that it also varies in the *direct ratio* of the force under which these actions occur; it is because these two necessarily vary in the same degree, one being dependent on the other, that the combined effect can be truly represented as due to the square of either one of them." Wherefore "Sigma" witnesses against himself when he says in his last letter, p. 669, "We all know that the energy expended in the circuit is in the ratio of the square of the E. M. F. Does it not follow naturally that the E. M. F. is really the square root of the energy?" He has himself shown that it is not so. Besides, if we consider that we may have any number of circuits expending the same amount of energy, but with very different values of the E. M. F. and current, it becomes self-evident that the E. M. F. cannot be an expression for the square root of the energy; otherwise we should have as many square roots as circuits! All this is the result of taking the current, or quantity transferred per second, as a fundamental phenomenon of electricity, instead of the quantity pure and simple, an error which leads to all sorts of laboured explanations why doubling E. M. F. without altering resistance does not double, but quadruples the electric energy. The plain fact is *that it does nothing of the kind.* What it *does* quadruple is *the energy set free per unit of time*, or, in other words, the rate of doing work; for in whatever degree the current is increased by an increase of E. M. F. a decrease of resistance, in that same degree is the time taken in the transfer of a given electric quantity decreased; so that electric energy is simply proportional to the electric quantity transferred and to the E. M. F. causing the transfer, as expressed by the formula W = EQ. And as these two things, E and Q, bear no sort of ratio to each other, it is clear that the energy is not really proportional to the square of either taken alone. E and C are proportional to each other simply on account of the nature of electric resistance, which is defined (B. A. Report, p. 69) as the quality of a conductor, in virtue of which it prevents the performance of more than a certain amount of work in a given time by a given electromotive force. It is not defined, be it remarked, either as a mechanical resistance, or by the amount of energy it dissipates; on the contrary, it is expressly stated (same page) that "Electrical resistance must not be looked on as analogous to a simple mechanical resistance, but rather to a coefficient by which the speed of the current must be multiplied to obtain the whole mechanical resistance. Thus, if the electrical resistance of a conductor be called R, the work W is not equal to CRt but C × CR × *t*, or W = C²Rt, where C may be looked on as analogous to a quantity moving at a certain speed, and CRt as analogous to the mechanical resistance which it meets with in its progress, and which increases in direct proportion to the quantity conveyed in the unit of time." Electrical resistance is, therefore, a perfectly definite property of matter, though its difference from what is usually meant by resistance has been clearly recognised long before "Sigma" claimed that difference as a heresy and paradox of his (letter 16718, p. 313). It is not, perhaps, surprising, if "Sigma" holds electromotive force to be a mere expression, having no actual existence, that he should seek to define it in terms of something which does actually exist, but I think he has not succeeded in doing so yet; and, moreover, the ground upon which he arrives at the above opinion seems to me more than doubtful. According to his first article (p. 101), this opinion is based on the assumption that E.M.F., though constantly acting on the circuit, has no accelerating action similar to that of gravity. I take this to refer to the absence of any increase in the current owing to a continued action of E.M.F. If so, "Sigma" is expecting what is not likely to take place. For E.M.F. (at least from one source) is only the affinity existing between any two molecules, and can continue to act only for the time the act of combination takes; when that is effected the force must necessarily cease to act, and as what we measure is the number of molecular changes, and not the actual molecular motion, we have no reason to expect any sort of acceleration. Doubtless, could we follow the motion of any molecule, we should find its velocity distinctly greater when the E.M.F. ceases than when it began to act.

I come now finally to the analogy "Sigma" finds between E.M.F. and the square root of head of water. Now, in order to explain and support an incorrect view of E.M.F., he appears to have invented a wholly imaginary mechanico-motive force, which, he says, "is seen to mean the same thing as the square root of head of water." If so, then head of water must be another of those remarkable things that have an indefinite number of square roots. For, according to "Sigma's" definition of mechanico-motive force, the current of water is to be considered equal to the product of

mechanico-motive force and conducting capacity; wherefore the same current will be produced whatever the value of those factors, provided they vary inversely as each other. But as "Sigma" also states that "head of water as a well-known fact in hydraulics, generates velocity, that is to say, current or flow of water, in the ratio of the square root of the head," it follows that, given a certain head of water, its square root, the so-called mechanico-motive force may be of any value we like. Truly an accommodating property! "Sigma" must pardon me for refusing to go further into the matter until such an inconsistency as this is removed. But the object of this surprising theory is gone if my preceding arguments have any truth in them; and, in fact, I cannot see why "Sigma" could not rest satisfied with the analogy, pointed out on p. 201 of his book, between the conditions of the closed circuit of a battery and a set of hydraulic machinery—an analogy as clearly shown as could be wished. Here the analogy of E.M.F. is the pressure of steam. I find also in the B.A. reports, p. 68, a clear analogy shown to exist between E.M.F. and head of water (that is to say, pressure), and not any imaginary square root thereof, and this also is perfectly satisfactory.

H. G. Moberly.

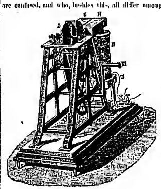
Finding the Mechanical Equivalent of Heat by Electro-Magnetism.

Oct Manufacturer & Builder

The strongest proof of the correctness of a numerical result is, undoubtedly, that the same figures are constantly arrived at when totally different means and principles are employed in the solution of a problem. Thus, in the case of the celebrated problem of the quadrature of the circle, the relation for the length of diameter and circumference of 1 to 3.14159265, etc., is obtained whether we use the elaborate method of approximations by calculating the periphery of polygons of many sides inscribed and circumscribed to the circle, or by calculating their surfaces; or if we apply trigonometry and calculate the arcs of given sines; or, again, if we apply the infinite series found by Leibnitz and others, or the continuous fractions expressing this relation; or, finally, the differential calculus—absolutely the same result is arrived at in each case, which is the best refutation to those circle squarers who either do not understand mathematics, or whose mathematical ideas are confused, and who, besides this, all differ among



Foucault's Electro-Magnetic Brake.

themselves, each obtaining a totally different number—the result of false reasoning.

The number of 772 foot-pounds for the equivalent of one unit of heat—first approximately obtained by Benjamin Thompson, and later more correctly by Joule and others—is in the same condition of absolute certainty. It means that 772 foot-pounds of force applied, and apparently destroyed by resistance, will reappear as one unit of heat—that is, will heat one pound of water one degree Fah. Thompson tried to obtain this relation by using horse power in the boring of cannon and measuring the quantity and temperature of the water he could heat by the friction produced. Joule in England used paddle-wheels immersed in water, oil, mercury, and other liquids, and put in rotary motion by means of a weight; the descent of the weight produced a corresponding ascent of temperature in the liquid agitated, and the heat measured and compared with the weight and its descent.

Mayer in Germany compressed air, and observing the heat generated by this compression, compared it with the power applied. The results of these observations, when carefully corrected for disturbing influences, (for which we have not space here to give in detail), produced results identical with the above mentioned figures.

Passing over other methods employed with the same purpose in view, such as friction between solids, which is one of the most common impediments to motion, and which always produces an amount of heat equivalent to the motion destroyed, we will only describe one of the most remarkable of this class, consisting in the application of resistance to mot[illegible] by magnetic attraction, without any fri[illegible]ct, but by a purely magnetic action throu[illegible]ervening space.

Arago first observed that when a copper disk is rapidly rotated under a compass needle, it acts on it at a distance and causes it to rotate also; while Faraday discovered that when a small piece of copper is suspended by a fine thread and made to whirl around, it will be arrested if a strong magnet is held near it, and when it is made to revolve by force the resistance of the magnetic action will cause it to become warm.

Foucault modified this experiment in such a way as to be able to compare the heat thus developed with the power applied. His apparatus is illustrated in the adjoined engraving, which is a representation of the form in possession of the Stevens Institute of Technology in Hoboken, N. J. It consists of a powerful electro-magnet B, of which the poles are turned upward, and provided with a soft iron armature that expands at both sides of a copper disk D, ¼ of an inch thick and 8 inches in diameter, and embraces nearly one-half of it, being as close to it as is practical without contact. To the disk a very rapid rotation may be given by means of the handle M and intervening gearing. When the electro-magnets are not charged, it is quite easy to make the disk turn with a velocity of from 150 to 200 revolutions per second; and when left to itself the motion will continue for some little time by the momentum of the moving parts; but if the current of a voltaic battery is caused to pass through the coils surrounding the electro-magnet, the motion will not only be instantly stopped, but a strong resistance will be felt when the handle is turned. When three Bunsen elements are used and the motion forcibly continued, the apparent destruction of the efforts will reappear as heat, and the temperature of the disk can be easily raised some 100°, while, by increasing the battery current sufficiently, the resistance may be made too great for a man to overcome.

A comparison between the heat thus obtained with the power applied, will, when reduced to units and descending weights, give the same result of 772 foot-pounds as equivalent to a unit of heat. Joule used a tube with water, having a thermometer inside, and rotated it forcibly between the armatures of the poles of a magnet, properly shaped to receive the tube. He found the same figures in a more direct manner than was possible with the disk.

The explanation of all this is that the magnetism develops induced circulating electric currents in any conducting mass moving under its attractive influence, and these currents develop heat, as is the case with all electric currents, while the amount of this heat depends on the strength of the currents and the resistance they undergo,

unless indeed that effect varies as the square of the

CORRESPONDANCE

—

Dans notre article relatif aux employés du télégraphe, nous avons mis le nom de Vesoul avec l'intention de savoir si des démarches seraient faites afin de découvrir l'auteur de la correspondance. Mais nous devons déclarer que la lettre nous est arrivée d'un point du territoire fort éloigné de celui que nous avons désigné. Les recherches, pour remonter à l'origine de cette lettre, seraient donc tout à fait infructueuses.

—

Les essais de la lumière Werdermann, faits à la demande du journal *l'Électricité*, ont eu lieu à plusieurs reprises la semaine dernière à l'usine de l'Alliance.

Nous avons reçu depuis lors plusieurs lettres conçues en des termes analogues, des abonnés qui avaient réclamé des lettres d'invitation.

Nous nous contenterons de reproduire celle qui nous a été remise la première.

Monsieur le directeur du journal *l'Electricité*,

Je vous remercie beaucoup, monsieur, pour la faveur que vous m'avez donnée de voir hier soir ce nouveau système de production de lumière tant simplifiée.

Le résultat actuel me paraît être déjà supérieur comme éclairage et plus économique que le système Jablochkoff.

Nous devons espérer le voir installer bientôt et entrer en compétence aux yeux du public parisien avec succès.

Recevez, etc.

F. GIRAUD,
80, rue des Batignolles.

Theory) L'Electricité

La substitution de « potentiel » pour « tension » La tension des pointes

Monsieur,

Permettez-moi de répondre à la lettre de M. du Moncel qui a paru dans votre dernier numéro. Il est vrai que dans ma lettre je débute en attaquant l'expression *tension d'un courant*, et qu'ensuite je défends le terme *tension*, pour lequel quelques mathématiciens ont voulu substituer le mot *potentiel*. Mais il n'est pas besoin de beaucoup de mots pour faire voir à M. du Moncel qu'il n'y a ici aucune contradiction. (Je dois observer en passant que l'expression *potentiel d'un courant* serait aussi dénuée de signification que celle qui a donné lieu à mon objection.) On pourrait, sans défaut de logique, protester contre l'expression *volume d'une surface*, et en même temps approuver le mot *volume* dans son application légitime. Un point, une surface, une charge statique peut avoir une tension; mais un *courant* — le résultat d'une différence de tension — ne peut aucunement lui-même avoir cet attribut. En effet, personne n'a jamais pu donner une définition de la tension d'un courant. Est-ce la tension d'un point quelconque dans le courant? Non, car ce point peut avoir une tension $+x$, ou $-x$, ou 0, et le courant reste constant. Est-ce la tension d'un des pôles de la source lorsque l'autre pôle est en communication avec la terre? Non, car alors un même courant pourrait avoir une infinité de tensions, puisque l'on peut obtenir le même courant avec toutes les sources et avec n'importe quelle tension au pôle en question. Est-ce la différence des tensions développées dans un circuit? Non, pour la même raison, et parce que cette différence constitue la force électro-motrice, et on ne dira pas que celle-ci s'appelle aussi *tension du courant*. Est-ce la différence des tensions mesurées aux extrémités d'une résistance constante? Non, car ceci constitue l'*intensité* d'un courant, ou la quantité d'électricité qui passe dans le circuit par seconde de temps.

Je remercie votre savant collaborateur — les opinions auquel, ici comme ailleurs, commandent toujours la plus grande considération — de sa déclaration que, selon lui, le potentiel et la tension ne sont pas deux propriétés différentes du fluide électrique. Or, pour exprimer une seule propriété, on n'a pas besoin, du moins dans la pratique, de deux termes, et il est clair que le mot *tension* jouit d'un droit de priorité qui devrait résister à toute innovation, pourvu qu'on ait soin de lui donner une définition exacte. Je ne veux pas parler d'une définition rationnelle ou physique, car la valeur de ce terme *tension* qui nous a été imposé par des mathématiciens est elle-même purement artificielle et ne représente que la *racine carrée* de la force électrique qui existe dans la nature. Mais si, faute de mieux, nous acceptons ce terme, pour éviter d'autres complications artificielles, nous devons lui donner les définitions suivantes :

1. La tension est la propriété de l'électricité qui se mesure par l'indication dite *électrométrique*. La tension peut être positive ou négative selon le signe de la charge de l'électromètre.

2. Posons :

$$E = \pm T - (\mp T_1)$$

Ici les deux tensions peuvent être (a) positives, (b) négatives, ou (c) l'une positive et l'autre négative; ce qui s'exprime par les deux signes qui précèdent T et T_1. Dans le cas (c),

$$E = + T - (- T_1) = T + T_1$$

Donc l'équation générale, dans les cas (a), (b), ou (c), pour l'une des tensions *maxima* dans tout circuit, conductive ou inductive, sera :

$$\pm T = E + (\mp T_1)$$

Et l'équation pour l'autre tension sera :

$$\mp T_1 = \pm T - E.$$

3. Posons $E = Q\ R$.

Soient r et r_1 deux résistances *inductives* en série dans un circuit (disons deux condensateurs ayant les capacités $c = \frac{1}{r}$ et $c_1 = \frac{1}{r_1}$). Alors $R = c + r_1$. Et, si nous supposons le circuit isolé, et que le pôle positif de la source soit en communication avec le condensateur ayant la capacité c, les tensions aux deux pôles seront :

$$+ T = Q\,r = \frac{Q}{c}, \text{ et } - T = Q\,r_1 = \frac{Q}{c_1}$$

J'arrive maintenant à une question qui m'a été posée par M. du Moncel, et qui a une très-grande importance théorique. Dans le cas d'un conducteur taillé en pointe et électrisé statiquement, il y a écoulement de l'électricité sur la pointe, sous la forme d'aigrette ou d'effluve silencieuse. « Or, « en vertu de quelle force cet écoulement aurait-il lieu, si ce « n'est par suite d'un excès de tension que le fluide possède « en ce point? » — Je réponds que l'écoulement a lieu en vertu de la *tension;* mais que néanmoins cette tension est absolument la même pour tous les points du conducteur. N'en déplaise aux calculs du mathématicien Poisson, s'il y avait différence de tensions d'un point à un autre dans le conducteur, un courant en résulterait qui aurait l'effet d'égaliser instantanément les tensions. Du reste, l'indication électrométrique est absolument la même quand l'électromètre est mis en communication avec la pointe ou avec toute autre partie du conducteur. Mais pourquoi alors y a-t-il écoulement par la pointe? Tout simplement, parce que la résistance conductive, ainsi que la résistance inductive, est très-faible à cet endroit du circuit. La loi est identiquement la même pour ces deux résistances (R et *R*); c'est-à-dire que la même cause qui produirait une variation de R amènerait une même variation de *R*. Or, l'accumulation ou la densité électrique, à un point quelconque du conducteur, sera $\frac{E}{R}$, si nous appelons *R* la résistance (inductive) qui s'oppose à l'accumulation de l'électricité sur ce point; et la perte électrique, par conduction, du même point à travers le diélectrique, sera $\frac{E}{R}$. Donc, si la densité électrique sur un point est très-grande, nous savons que la résistance conductive à ce point sera très-faible, et qu'il y aura perte d'électricité sur ce point. Et, puisque nous savons que la densité électrique sur les pointes est comparativement énorme, et que cette densité résulte de la faible résistance inductive qui s'oppose à l'accumulation, il n'y a pas lieu de s'étonner s'il y a écoulement d'électricité par les pointes, car la résistance conductive doit être également faible.

Mais, d'ailleurs, il est facile de prouver, par les lois élémentaires de conduction, que la résistance qui s'oppose au passage de l'électricité par une pointe, doit être compara-

Les subtilités de la science électrique en Allemagne

L'Electricité

Le numéro de juillet des *Annales de Poggendorf* contient un mémoire de M. Helmuotz sur *les couches limites de l'électricité*, qui occupe une cinquantaine de pages en tête de la livraison.

Ce travail a déjà paru par extrait dans le journal mensuel de l'Académie de Berlin, mais il était évidemment indispensable que les physiciens d'outre-Rhin pussent juger de l'ensemble d'un si remarquable document.

Dans une espèce d'introduction que nous demanderons à nos lecteurs la permission de ne point reproduire, il explique qu'il ne se contente pas, comme ses prédécesseurs, d'étudier les effets à distance de l'électricité, mais qu'il se préoccupe de déterminer l'épaisseur de la couche électrisée.

Appelant D la distance d'une plaque de cuivre, *e* la densité de l'électricité positive répartie à la surface, l'auteur pense que le produit *e* D est une quantité constante qu'il nomme le moment de la couche électrisée.

C'est en partant de cette considération que M. Helmuotz cherche à faire, à l'aide du potentiel, ce que nous nommerons l'anatomie idéale de la couche électrisée.

Dans cette partie de son travail, l'auteur s'appuie sur des recherches de Clausius et de sir William Thompson, démontrant que les molécules des gaz se bombardent l'une l'autre avec une vitesse de 50.000 centimètres par seconde, que le nombre des collisions entre ces deux molécules invisibles est de cinq cent-millioniémes de seconde, de sorte que le chemin moyen parcouru dans cet incessant bombardement est de la cent-millième partie d'un millimètre.

L'auteur suppose encore que par des raisons d'une clarté éblouissante, le nombre des molécules du gaz ne peut excéder 25 millions dans un globe dont le diamètre est précisément un cent-millième de millimètre. Il en tire la conclusion que le volume réel des molécules bombardantes ne peut être moindre que un cinq cent-millionième de centimètre et que par conséquent un centimètre cube d'air à la dureté ordinaire ne doit pas renfermer plus de six mille millions de molécules.

Combien nous regrettons que le défaut d'espace nous empêche d'entrer dans le développement de principes aussi utiles, pour le moins aussi féconds pour l'électricité que le Bathybius du grand docteur Hæckell l'a été pour l'histoire naturelle.

Dans les autres parties de son œuvre, M. Helmuotz applique ces beaux principes aux mouvements des liquides à travers des cloisons poreuses quand il s'agit aussi bien de piles que de décharges de bouteilles de Leyde.

Malheureusement, l'auteur ayant oublié de conclure, nous ne nous chargerons point de nous acquitter, pour son compte, de cette formalité.

—

Laplace s'était préoccupé dans sa *Mécanique céleste* des altérations lentes que la résistance du fluide éthéré pouvait produire sur les mouvements de la Terre et de la Lune.

Ce prophète de l'astronomie officielle ayant établi, à la fin du troisième volume de son Code des *Lois du Ciel*, que cette cause perturbatrice produit sur le mouvement de la Terre un effet cent fois moindre que sur le mouvement de la Lune, il semblait que les physiciens dussent laisser l'éther en repos.

Mais sir William Thompson s'est avisé, il y a déjà pas mal de temps, de peser par le calcul la masse du fluide éthéré qui doit remplir un pouce cube anglais.

En employant des procédés aussi simples, aussi clairs, aussi précis que ceux de M. Helmuotz, sir William est arrivé à la formule

$$\frac{83\,g}{V^2 n^2}$$

expression dans laquelle g indique l'intensité de la gravitation, n la vitesse d'oscillation des particules d'éther et V la vitesse de propagation de la lumière.

La vitesse de la lumière peut être considérée comme connue par des expériences directes telles que le retard des éclipses des satellites de Jupiter. Quant à la vitesse d'oscillation des molécules d'éther, l'auteur du siphon enregistreur n'a pu concevoir un mécanisme susceptible de le mettre en évidence.

Mais un grand analyste ne s'arrête pas pour si peu de choses, et il a bravement annoncé que cette vitesse devait être de 1/50 de pied anglais.

En faisant cette hypothèse gratuite, sir William est arrivé à exprimer en livres anglaises le poids de la quantité d'éther contenue dans un pied cube anglais. En multipliant par 30 et réduisant en kilos, nous trouvons que pour avoir six kilos d'éther, il faudrait ramasser celui qui se trouve dans

2 700.000.000.000.000.000 mètres cubes.

Comme les mêmes auteurs, toujours avec l'appui des grands penseurs, tels que le célèbre Zölner de Leipzig, ont établi que la lumière et l'électricité sont une même chose, et que l'éther est le factotum de la physique, nous ne saurions exagérer l'importance de si surprenants résultats.

Aussi les lecteurs de l'*Electricité* n'apprendront-ils point sans quelque désappointement que M. P. Glan trouve que sir William s'est trompé.

Ce qui les consolera peut-être, c'est que ce savant rédacteur des *Annales de Poggendorf* a démontré que la matière éthérée est beaucoup moins rare dans le monde que sir William l'a imaginé.

En effet, il établit toujours par des raisonnements irréfragables que la descente du milieu éthéré est *sept mille quatre cent seize fois* plus grande que sir William ne l'a établi.

Que diront les héritiers de Laplace en voyant qu'on augmente à ce point la densité du milieu dans lequel les astres doivent éternellement tourner sans se fatiguer?

Ce n'est point à nous qu'il appartient de nous en inquiéter.

DIAMAGNETISM.

[16?]—I am surprised to find so good a correspondent as "J. B." teaching the scholastic nonsense involved in diamagnetism.

Given a pair of scales, with 8oz. in one pan and 7oz. in the other, and the first weight will descend, but with 9oz. in the other pan it will ascend. Now, we do not say that this weight herein evinces "antithetic" properties,—that while descending it is the analogue of a magnetic, that while ascending it has an opposite quality, corresponding to a diamagnetic; yet this is precisely what Tyndall has contended for in diamagnetism, and which Faraday resisted almost to a quarrel.

Given a field of gravitating force and two balloons, one filled with carbonic acid gas, the other with hydrogen. The former would descend in air, while the latter would ascend, and for reasons too plain to require specification.

Given a field of magnetic force from one pole, let us imagine two small soap-bubbles filled with oxygen and hydrogen gases. The former would be attracted and the latter repelled, because the former is a better conductor of polar force than air, while air is a better conductor than hydrogen. The lines of force would be *alike* in both cases, but stronger in one case and weaker in the other. Faraday has beautifully shown how the lines of force behave in such cases, accumulating or condensing in the one case, and weakening or opening out in the other.

Given with iron solution a liquid field of force between two magnetic poles, let us suspend from their centres two small tubes of iron solution, one stronger than the medium (*a*), the other weaker (*b*). In air, of course, both would be magnetics, and point axially between the poles; but in the fluid (*a*) would be a magnetic, and (*b*) a so-called diamagnetic. If we imagine both placed alike in the axial position, the lines of force would condense in (*a*), and therefore involve stable equilibrium in that position; but the lines in (*b*) would open out, or become weaker, relative to the corresponding condensation in the better conducting medium, and therefore involve *unstable* equilibrium; so that when free to move, as from a centre, it would be displaced towards a transverse equilibria; or, to use the expressive words of Faraday (although he never grasped the full meaning), "Magnetics tend to place themselves in the lines of strongest force, while diamagnetics tend to occupy the lines of weakest force."

Now, I would ask "J. B.," in regard to these tubes, while placed in the axial position and not free to move, can he imagine that the polarities, apart from quantity or strength, are normal in (*a*) and inverted or "*antithetical*" in (*b*)?

We know that (*b*) is a magnetic substance *per se*, and to suppose that at one moment it can react with a normal or opposite polarity, in relation to the inducing poles; and that at another moment it can react with an opposite, opposite polarity (the reverse of the former) is an outrageous hypothesis, as inimical to common-sense as it is incompatible with all observed facts.

I have tried to speak plainly and strongly; because, when error becomes *fashionable* and is taught in all the manuals, it is very difficult to dislodge it, and the more so when such vague and scholastic arguments are put forth in its support, and metaphysical mathematics have been largely subsidised.

But while the schools, manuals, and third-rate teachers will go on, some new facts have transpired which justify the prediction that from such good men as Tyndall we shall have but little more of diamagnetic disquisition.

What we have seen to subsist with gravitating weights and balloons, as with magnetic good and bad conductors of polar force, is now similarly proved for electrical action; and taking a battery field of force, or rather of action, as between the — and + plates, it is now found that we may insert, by a middle suspension, small bars of different substances, when better conductors of the electrolytic action, take an axial position, while worse conductors are deflected into the lines of weakest force, or, in other words, they tend to a transverse equilibria.

We have long recognised good and bad conductors for sound, light, heat, and electricity; let us be equally fair in admitting the same for magnetism or polar force, and out of confusion and complexity comes order and simplicity.

Eclectious.

THE NATURE OF ELECTRICITY[1]

ON surveying the wide sea upon which the numerous and varied practical applications of electricity are launched for the subject of this evening's address, I have been puzzled to steer a course that shall avoid the dazzling shoals of theory on the one hand, and the dry hard rocks of practice on the other.

[1] Abstract of the Inaugural address to the Society of Telegraph Engineers, by Mr. William Henry Preece (President), delivered January [illegible], 1880. Revised by the Author.

Hypothesis is a veritable Scylla that captivates the imagination and often sends the visionary to destruction, while practice alone is a hard-hearted Charybdis that lures the matter-of-fact practical man to folly and expense. Practice must be tempered with theory to utilize advantageously the great forces of nature, and theory itself must be based on practice, or on facts, to be comprehensive and acceptable. Hence success is the off-spring of the marriage of practice and theory, and, therefore, as the two are so intimately connected, I have determined to steer a middle course to-night to survey the progress of each in our profession, and to show their mutual relationship.

What is theory? It is an explanation of the hidden cause of certain effects that are evident to the senses. It is an effort of the imagination to account for operations that are in themselves invisible and insensible, but which result in facts that are observable and known. Thus the movements of all those bright bodies by which

> "the floor of heaven
> Is thick inlaid with patines of bright gold,"

are explained by the theory of gravity. Their appearance, vagaries, and beauties are accounted for by the undulatory theory of light. The warmth that the monarch of them all shed upon this earth countless ages ago, and that is now restored to us in our household fires, is explicable on the molecular theory of heat. The constitution of matter and its various states of solid, liquid, and gas, are completely explained by the atomic theory of Democritus and Dalton, and the modern kinetic theory of gases.

It is impossible for a practical man who has devoted more than a quarter of a century to the application of electricity to useful purposes, to avoid devoting much contemplation to the nature of the agent which he has to make use of. Is there a member of this society who has not striven to peer into the region of the unknown, who has not speculated on the power he uses, or who has not formed some conception in his mind of the nature of electricity? Yet it is remarkable that the answer to the question, What is electricity? cannot even now be given with authority. Faraday, our great apostle, whose researches should be every electrician's bible, declined to venture an answer, nor did he ever directly formulate his ideas on the subject, though his publications indicate pretty clearly and with no uncertain sound what they were. Clerk-Maxwell, who, while he overthrew all existing theories, failed to supply their place before he was so untimely removed from us. Sir William Thomson, in his published papers, always carefully eschews the consideration of any physical theory of electricity. The French electricians simply use the one-fluid theory as a convenience of language, while the Germans, as a rule, employ the two-fluid theory merely for mathematical purposes. Hence there is no recognised theory of electricity. Some maintain with Du Fay or with Franklin, that it is a form of matter—a substance; others, following Faraday and Grove, consider it a form of force—a motion—like heat and light. It must be either one or the other. There is no other category in which to class it. If it is not a form of matter it must be a form of force. The question I propose to discuss is, therefore, Is electricity a form of matter, or is it a form of force?

In discussing such a vexed question it is necessary to be very precise in language to avoid any misconception of my meaning, therefore I will define both matter and force in the sense in which I use those terms. *Matter* is that which can be perceived by the senses, or can be acted upon by force. It is characterised by weight, inertia, and elasticity. *Force* is that which produces, or tends to produce, the motion of matter. It may be pressure, tension, attraction, repulsion, or anything capable of causing alteration in the natural state of rest or of existing motion of matter.

Matter is found in either the solid, liquid, gaseous, or ultra-gaseous state, and it occupies space. It consists of molecules and atoms. The *atom* is the smallest indivisible part of an element, and a group of atoms of the same or of different elements forms the *molecule*, which has a definite magnitude and is unalterable in form for each substance. The *mass* of a substance is the aggregate of the molecules of which it is composed. There is no generation or destruction of atoms. The indestructibility of matter is a fixed law in nature. The size of the molecule is approximately known. Sir William Thomson says:—"If we conceive a sphere of water as large as a pea to be magnified to the size of the earth, each molecule being magnified to the same extent, the magnified structure would be coarser-grained than a heap of small lead shot, but less coarse-grained than a heap of cricket balls." Fifty million molecules ranged in single file would occupy an inch. They are highly elastic, and unless interfered with would move with constant velocity in straight lines. When they can move about freely without interfering with each other's proceedings, we have the ultra-gaseous state of Crookes, a state found only in very high vacua and under certain adventitious circumstances. When they collide and impinge on each other according to the law of the impact of elastic bodies, interfering with each other's path, we have *gases* as we know them; when their mean free path is so reduced as to bring them within the sphere of mutual attraction, without too narrowly restricting their play, we have *liquids*; when the attraction becomes cohesion and the motion of the molecule is confined to its own sphere, we have *solids*. The number of molecules in a given volume of gas is known, and their velocity calculated. In hydrogen the velocity at 0° Cent. is 6,097 feet per second, the number being [illegible] per cubic inch. The mean free path of a molecule in air at ordinary pressures is the ten-thousandth part of a millimetre. Besides their constant motion in straight lines the molecules may be set in vibration, rotation, or any other kind of relative motion whatever.

This is the atomic theory of matter born in the brain of Democritus, "the laughing philosopher," 2,300 years ago; preached by Epicurus in Athens, and taught by Lucretius in Rome before the Christian era; lying dormant for eighteen centuries, until it was formulated by Dalton in the last century, and removed from the region of pure speculation by Joule, Clausius, Clerk-Maxwell, and Crookes during our days.

The definition of force shows us that whatever changes or tends to change the motion of matter (or of the molecules of which it is composed), by altering either its direction or its magnitude, is a form of force. Thus gravity is a form of force, for it attracts all matter to the centre of the earth, and it is measured by the rate per second at which a body acquires a velocity in this direction when falling freely at a given spot. Heat is a form of force, for it throws the molecules of matter into violent vibration, or it increases the velocity of their motion in straight lines, which thus becomes the measure of its heat or its *temperature*. Light is a form of force, for it is produced by the undulation of the molecules of matter, and it is transmitted by the undulations of that medium called Ether, which fills all space.

When we take a given free mass and impress upon it a given force, we throw that mass into motion; for instance, when we fire a loaded cannon, we have imparted to the ball "*energy*," and in virtue of the motion of the ball, this energy is called "*kinetic*." Again, if we lift the ball to a certain height above the earth's surface—say to the top of a tower—and let it remain there, we have again imparted to it "energy," but this time it is called "*potential*," for it is dormant or resting. In each case the energy possessed by the ball is the exact equivalent of the work done upon it, that is, of the force impressed and the distance through which it has acted. The motion of the ball is readily transferred to the motion of the individual molecules of the ball. When, in the first case adduced, the ball strikes the side of a ship or a target, its kinetic energy is thus converted into light and heat, which is molecular motion; or, in the second case, when it is allowed to fall, its potential energy is converted into kinetic energy, which again, on coming in contact with the ground, is converted into molecular motion or heat. Energy is always either potential or kinetic, and one of the most remarkable generalisations of modern days is the grand principle of the conservation of energy, which implies that the total energy of the universe is a quantity which can neither be increased nor diminished, though it may be transformed into any of the forms of which energy is susceptible. Energy is therefore as indestructible as matter. All the recent advances in the science of heat have been due to the discovery of this principle, and its application to electricity has gone far to remove that science from the hypothetical state in which it has existed so long.

My purpose is to contend that electricity is not a form of matter but a form of force, and that all its effects are evident to us in one or other of the several forms of energy characterised by the motions of molecules or of mass.

It is interesting to trace the historical growth of theories. The uncultivated human intellect cannot soar above its own limited sphere of childish observation. Whatever is mysterious and incomprehensible in nature is attributed to that which is equally mysterious and incomprehensible. Life has ever been of this character, and heat, magnetism, electricity, and many

unless indeed that effect varies as the square of the

Some recent very remarkable researches of M. Planté with his rheostatic machine[1] have shown that fine wires conveying powerful currents are wrinkled up into well-defined regular nodes, that [illegible] accompanied by a peculiar crackling, and that the [illegible] giving clear indication of the vibratory [illegible] gives as the result of his inquiry that electrical transmission is the result of a series of very rapid vibrations of the more or less elastic matter which it traverses, and he points out certain analogies between electric motion and sonorous vibrations. This view is supported by the researches of Professors Ayrton and Perry[2] on the viscosity of dielectrics.

Prof. Challis, of Cambridge, has extended this view so far as to embrace magnetism, electricity, light, heat, and gravity in one category of physical force, and to assert that they all result from motions and pressures of a uniform elastic fluid medium pervading all space not occupied by atoms. His views, however, have not received much attention, for they are not based on the foundation of any new facts, and they are utterly subversive of many cherished principles deeply rooted in the scientific mind. It is to be observed, however, that he regards electricity as a form of force.

Mr. Crookes, in his recent beautiful experimental researches into molecular physics in high vacua, has still more conclusively proved the connection that exists between electrical action and molecular motion. In fact, his experiments are so brilliant, his expositions so lucid, that one can fancy one sees with the eye of the body that peculiar play of the molecules which can be evident only to the eye of the mind. Not only has Mr. Crookes established as a physical fact the kinetic theory of gases and the molecular constitution of matter, but he has indicated the existence of a fourth state of matter where the molecules fly about without mutual let or hindrance. He has also led us to doubt the truth of the generally received opinion that an electric current flows from the positive to the negative electrode. It would appear from his investigations that the reverse is the case. Be that as it may, he has added one story to the structure of the molecular theory of electricity.

The criterion of a good theory is, however, its power of prediction. A false theory has never led to prevision. Neither the corpuscular theory of light, nor the fluid theories of heat and electricity, ever led to the prediction of something of which eyes had not seen nor ears heard. The triumphs of prediction in astronomy, sound, light, and heat are innumerable. Faraday predicted the effect of induction in lowering the velocity of currents of electricity and the action of magnetism on a ray of light. Sir William Thomson predicted that a current in passing from a hot to a cold part of a copper bar would heat the point of contact, while to an iron bar it cools it. Peltier predicted the cooling effect of currents on the junctions of thermoelectric pairs.

But the true identity of these physical effects is conclusively shown by their quantitative character and by their adhesion to the law of the conservation of energy. Take the case of the electric light: the consumption of coal in a furnace generates steam, the steam works an engine, the engine rotates a coil of wire in a magnetic field, the motion of the coil in this field induces currents of electricity in the wire, these currents of electricity produce an arc, and thereby heat and light. The energy of the coal is transformed into heat and light through the intermediate agency of electricity. Is it possible to conceive that this intermediate agency is anything but a form of energy? Take the case of the Bell telephone: the energy of the voice produces the energy of sonorous vibration in the air, the vibrations of the air cause the vibrations of the iron disk, the vibrations of the disk vary the magnetism of the magnetic field, this produces currents of electricity in a small coil in this field which vary the magnetism of the distant magnet, which in its turn throws its disk armature into vibration, and thereby repeats at the distant station the sonorous vibrations of the air, and thus reproduces the energy of the voice. A tuning fork comes to rest sooner in front of a telephone than when it is allowed to vibrate freely in air. Here we have the energy of the fork passing through the several stages indicated above, and ultimately coming out in its original form. The energy of sonorous vibrations at the distant station is that lost by the vibrating tuning fork.

Is it possible to assume that in this cycle of changes energy has been transformed into matter and matter again formed into energy? It is impossible and absurd. Clerk-Maxwell said—

"When the appearance of one thing is strictly connected with the disappearance of another, so that the amount which exists of the one thing depends on and can be calculated from the amount of the other which has disappeared, we conclude that the one has been formed at the expense of the other, and that they are both forms of the same thing."

Would it be possible to light the streets of New York by the energy of the falling water at Niagara, as has been suggested by our Past President, Dr. Siemens, if the cycle of changes from the one spot to the other were not all different forms of this same energy? Would it be possible to plough a field a mile away from the source of motive power of the transmitting medium if the electric currents were not forms of the same power? Electricity in its effects is and must be a form of energy.

The final stage into which any physical theory grows is that in which every action can be expressed in mathematical language, where every phenomenon is calculated upon an absolute physical basis, and where we can foretell exactly what will occur under any possible emergency. This is the present condition of the science of electricity. We can calculate exactly how much steam power is required to generate a given current to produce a given light. We can tell precisely what dimensions of cable are necessary to give a certain number of words per minute on the other side of the globe. If a fault develop itself in a long cable through the gastronomic propensities of a thoughtless young teredo, we can calculate to within a few fathoms the locality of his edacious depredation.

Clerk-Maxwell,[3] in his classical work on electricity, has used a somewhat curious argument to show that electricity is not, like heat, a form of energy. He says that energy is produced by the multiplication of "electricity" and "potential," and that it is impossible that electricity and energy should be quantities of the same category, for electricity is only one of the factors of energy, the other factor being "potential." But this does not militate in any way against the force of the argument, for in nature we can no more do so than we can separate heat and temperature. Energy usually appears as the product of two factors, and it is the equivalent of the work done. Thus, *Potential energy* is the product of mass and gravitation acting through a distance. *Kinetic energy* is the product of mass and the half-square of velocity. The energy of fluids is the product of volume and pressure. The energy of heat is made up of heat and temperature, and the energy of electricity is the product of electricity and potential. Hence it is that electricity, *per se*, may be said to be a form of force, while all its effects as known to us are forms of energy. Force alone cannot produce energy; it must be force and something else. Force is the power of producing energy, and it must have something on which to produce it. Hence matter is always present; and thus, though heat, light, and electricity are forms of motion, they are in reality properties of matter from which they are inseparable. They are evident to us through the play of the molecules of matter, and thus are properly called molecular forces.

Earth currents have been a favourite subject of inquiry of mine for many years. I have always entertained the idea that they are directly due to the action of the sun. Some disturbance in the sun causes, by induction, a variation in the distribution of the lines of potential on the earth's surface, and produces the conditions required for these currents. I have many facts to support this hypothesis, but I want more to confirm it. Profs. Ayrton and Perry have developed a theory of terrestrial magnetism based on the assumption that the earth is a highly electrified sphere, which not only coincides well with facts, but which tends greatly to support my views. I want observers to record the times of daily maxima and minima. I want them especially to note during those periods of unusual disturbance the direction of the circuits which are *not* affected, for they would give the direction of the lines of equi-potential. This not only offers a useful field of observation, but its failure or success will illustrate the modern method of scientific research, when the brain suggests to the hand and the eye what they have to do, and what they have to look for.

Mr. Preece then went on to speak of the educational work of the Society and to notice some of the recent practical applications of electricity, and in speaking of the telephone stated that litigation has commenced between the Post-Office and the telephone companies not to restrict or in any way to interfere with the use of the telephone, but to prevent the establishment of a

Scientific American Jan 17 1880

To the Editor of the Scientific American:

It would seem that the authors of books and chapters on electricity are largely culpable for the numerous discussions which have appeared of late in the SCIENTIFIC AMERICAN on electrical generators. The problem to find the maximum current with a given lot of battery cells and external resistance is well known; also the answer to it, viz., internal resistance equal external resistance. But the other problem, viz., to find, with given external resistance, the number and arrangement of cells, for procuring a given current with a minimum consumption of zinc, seems to be far less common in books, and perhaps generally, though the result may often be of far greater importance.

To illustrate, suppose that in some electro-plating establishment a plating bath is so run as to offer about constant resistance to current; and suppose a certain standard constant current is preferred. If these conditions can be realized by one arrangement requiring $25 greater outlay in first cost for increasing the number of cells, whereby a saving of $50 a year for zinc is realized; a party, expecting to run for years, would be quite likely to adopt the greater first cost.

What is true in consumption of zinc in batteries will be true, in some measure at least, in dynamo-electric machines, because the zinc consumed in one case represents energy, and so do the foot pounds consumed in the other. Hence, for simplicity, batteries are here considered instead of machines.

That for a given external resistance a given current strength may be maintained by different arrangements of cells in rows, the total number of cells varying as required, is evident from considerations of Ohm's law. For instance, if 100 cells in 5 rows satisfies a certain current and resistance, the same effect may be secured with 10 rows of batteries, though 40 or 60 cells may be necessary. It may happen, however, that a large percentage of zinc will be saved with the 60 cells and 10 rows.

The energy of a current is stated, on good authority, to be proportional to the zinc consumed in a well conditioned battery; also, it is proportional to the electro-motive force multiplied by the current strength. These facts applied so as to bring about the relation between the zinc consumed in different cases will show that *for the same external resistance the weight of zinc consumed in a battery arranged for maximum current; divided by the weight of zinc consumed in a battery by like cells in greater number for an equal current, is simply equal to the number of cells in one row of the first battery, divided by the number of cells in one row of the second battery.*

Also for the relation of numbers of cells, it will be found that the ratio of the number of cells in one row, 1st battery and 2d, added to the ratio of number of rows, 1st battery and 2d, is equal to 2; also, the maximum value of this 1st ratio can never be greater than 2.

An example will serve to fix the ideas: Let the cells of battery considered be all alike, with equal electro-motive forces, and the internal resistance of each equal 1 ohm; let the external resistance equal 4 ohms. If the number of cells be 144, arranged in 24 rows of 6 each, we have the maximum current for the cells of resistance named. Again, if 192 like cells be arranged in 12 rows of 16 each, we will have the same current strength, though the total internal resistance of the 2d will be only a third of the 1st.

According to the rule above, the consumption of zinc in the 1st battery will be 50 per cent greater than in the 2d.

Hence it appears that the best arrangement of a battery of several cells for maximum of current is one thing, while the best number and arrangement for securing a given current with a minimum of zinc is quite another. The quantity of zinc diminishes with internal resistance.

From the fact that zinc consumption in a battery stands for about the same thing as foot pound consumption in the dynamo electric machine, it would seem that for the minimum of power the internal resistance of the machine should be reduced to as small a fraction of the whole as possible, the size of the machine and conditions of working being, of course, consistent with the given current required.

S. W. ROBINSON,

their nonnings.

ON THE ELECTROMOTIVE FORCES WHICH APPEAR IN FREE JETS OF WATER.—Electrician April 24 1880 — Elster considers his investigations proved, if an electromotive force is to arise in a free jet of water, it is necessary that the water particles be in contact with a solid body. That the evolution of electricity takes place only where the particles of the liquid undergo friction, so that only a relatively small portion of the water-jet contributes any thing to the development of electricity. That when the velocity of a jet issuing constantly from the same orifice is varied, the electromotive forces are proportional to the *vires vivæ* of the liquid particles—a relation the reason of which is found in the law of the conservation of energy. And, lastly, that the electromotive force is dependent on the nature of the body which is in contact with the liquid. From these results the author draws the following conclusions:—The motion of a fluid does not by itself produce any electromotive force. Consequently the inference deduced by Edlund from his unitary theory of electricity has not been confirmed. Capillary electric currents are conditioned solely by the friction of the particles of the fluid in motion—in nonhumectant fluids by their friction against the particles of the solid wall, in humectant fluids by friction on the particles of a layer of the same fluid condensed upon the surface of the solid body, which behaves towards the less dense layer like a heterogeneous substance. The capillary-electric currents discovered by Quincke are identical with the friction-currents, first observed by Zöllner, which make their appearance in the rubber of an electrical machine.

ON A NEW ACTION OF THE MAGNET ON ELECTRIC CURRENTS.

Electrician March 13 1880

By E. H. HALL, Fellow of the Johns Hopkins University.

Sometime during the last University year, while I was reading "Maxwell's Electricity and Magnetism" in connection with Prof. Rowland's lectures, my attention was particularly attracted by the following passage in Vol. II., p. 144.

"It must be carefully remembered that the mechanical force which urges a conductor carrying a current across the lines of magnetic force, acts, not on the electric current, but on the conductor which carries it. If the conductor be a rotating disc or a fluid it will move in obedience to this force, and this motion may or may not be accompanied with a change of position of the electric current which it carries. But if the current itself be free to choose any path through a fixed solid conductor or a network of wires, then, when a constant magnetic force is made to act on a system, the path of the current through the conductors is not permanently altered, but after certain transient phenomena, called induction currents, have subsided, the distribution of the current will be found to be the same as if no magnetic force were in action. The only force which acts on electric currents is electromotive force, which must be distinguished from the mechanical force which is the subject of this chapter."

This statement seemed to me to be contrary to the most natural supposition in the case considered, taking into account the fact that a wire not bearing a current is in general not affected by a magnet, and that a wire bearing a current is affected exactly in proportion to the strength of the current, while the size and in general the material of the wire are matters of indifference. Moreover, in explaining the phenomena of statical electricity it is customary to say that charged bodies are attracted toward each other, or the contrary, solely by the attraction or repulsion of the charges for each other.

Soon after reading the above statement in Maxwell I read an article by Prof. Edlund, entitled, "Unipolar Induction" (*Phil. Mag.*, Oct., 1878, or *Annales de Chemie et de Physique*, Jan., 1879), in which the author evidently assumes that a magnet acts upon a current in a fixed conductor just as it acts upon the conductor itself when free to move.

Finding these two authorities at variance, I brought the question to Prof. Rowland. He told me he doubted the truth of Maxwell's statement, and had some time before made a hasty experiment for the purpose of detecting if possible some action of the magnet on the current itself, though without success. Being very busy with other matters, however, he had no immediate intention of carrying the investigation further.

I now began to give the matter more attention and hit upon a method that seemed to promise a solution of the problem. I laid my plan before Professor Rowland, and asked whether he had any objection to my making the experiment. He approved of my method in the main, though suggesting some very important changes in the proposed form and arrangement of the apparatus. The experiment proposed was suggested by the following reflection:—If the current of electricity in a fixed conductor is itself attracted by a magnet the current should be drawn to one side of the wire, and, therefore, the resistance experienced should be increased.

To test this theory, a flat spiral of German silver wire was enclosed between two thin discs of hard rubber, and the whole placed between the poles of an electro-magnet in such a position that the lines of magnetic force would pass through the spiral at right angles to the current of electricity.

The wire of the spiral was about ½ millim. in diameter, and the resistance of the spiral was about two ohms.

The magnet was worked by a battery of twenty Bunsen cells, joined four in series and five abreast. The strength of the magnetic field, in which the coil was placed, was probably fifteen, or twenty thousand times H, the horizontal intensity of the earth's magnetism.

Making the spiral one arm of a Wheatstone bridge, and using a low resistance Thomson galvanometer, so delicately adjusted as to betray a change of about one part in a million in the resistance of the spiral I made, from October 7th to October 11th inclusive, thirteen series of observations, each of forty readings. A reading would first be made with the magnet active in a certain direction, then a reading with the magnet inactive, then one with the magnet active in the direction opposite to the first, then with the magnet inactive, and so on till the series of forty readings was completed.

Some of the series seemed to show a slight increase of resistance due to the action of the magnet, some a slight decrease, the greatest change indicated by any complete series being a decrease of about one part in a hundred and fifty thousand. Nearly all the other series indicated a very much smaller change, the average change shown by the thirteen series being a decrease of about one part in five millions.

Apparently, then, the magnet's action caused no change in the resistance of the coil.

But though conclusive, apparently, in respect to any change of resistance, the above experiments are not sufficient to prove that a magnet cannot affect an electric current. If electricity is assumed to be an incompressible fluid, as some suspect it to be, we may conceive that the current of electricity flowing in a wire cannot be forced into one side of the wire or made to flow in any but a symmetrical manner. The magnet may *tend* to deflect the current without being able to do so. It is evident that in this case there would exist a state of stress in the conductor, the electricity pressing, as it were, toward one side of the wire.

Reasoning thus, I thought it necessary, in order to make a thorough investigation of the matter, to test for a difference of potential between points on opposite sides of the conductor.

This could be done by repeating the experiment formerly made by Prof. Rowland, and which was the following:—

A disc or strip of metal, forming part of an electric circuit, was placed between the poles of an electro-magnet, the disc cutting across the lines of force. The two poles of a sensitive galvanometer were then placed in connection with different parts of the disc, through which an electric current was passing, until two nearly equipotential points were found. The magnetic current was then turned on and the galvanometer was observed, in order to detect any indication of a change in the relative potential of the two poles.

Owing probably to the fact that the metal disc used had considerable thickness, the experiment at that time failed to give any positive result. Professor Rowland now advised me, in repeating this experiment, to use gold leaf mounted on a plate of glass as my metal strip. I did so, and, experimenting as indicated above, succeeded, on the 28th of October, in obtaining, as the effect of the magnet's action, a decided deflection of the galvanometer needle.

This deflection was much too large to be attributed to the direct action of the magnet on the galvanometer needle, or to any similar cause. It was, moreover, a permanent deflection, and therefore not to be accounted for by induction. The effect was reversed when the magnet was reversed. It was not reversed by transferring the poles of the galvanometer from one end of the strip to the other. In short, the phenomena observed were just such as we should expect to see if the electric current were pressed, but not moved, toward one side of the conductor.

In regard to the direction of this pressure or tendency as dependent on the direction of the current in the gold leaf and the direction of the lines of magnetic force, the following statement may be made:—If we regard an electric current as a single stream flowing from the positive to the negative pole, *i.e.*, from the carbon pole of the battery through the circuit to the zinc pole, in this case the phenomena observed indicate that two *currents* parallel and in the same direction tend to repel each other. If, on the other hand, we regard the electric current as a stream flowing from the negative to the positive pole, in this case the phenomena observed indicate that two *currents* parallel and in the same direction tend to attract each other.

It is, of course, perfectly well known that two *conductors* bearing currents parallel and in the same direction are drawn toward each other. Whether this fact, taken in connection with what has been said above, has any bearing upon the question of the absolute direction of the electric current it is perhaps too early to decide.

In order to make some rough quantitative experiments a new plate was prepared, consisting of a strip of gold leaf about 2 cm. wide and 9 cm. long, mounted on plate glass. Good contact was ensured by pressing firmly down on each end of the strip of gold leaf a thick piece of brass polished on the under side. To these pieces of brass the wires from a single Bunsen cell were soldered. The portion of the gold leaf strip not covered by the pieces of brass was about 5½ cm. in length, and had a resistance of about 2 ohms. The poles of a high-resistance Thomson galvanometer were placed in connection with points opposite each other on the edges of the strip of gold leaf, and midway between the pieces of brass. The glass plate bearing the gold leaf was fastened, as the first one had been, by a soft cement to the flat end of one pole of the magnet, the other pole of the magnet being brought to within about 6 mm. of the strip of gold leaf.

The apparatus being arranged as above described, on the 12th of November a series of observations was made for the purpose of determining the variations of the observed effect with known variations of the magnetic force, and the strength of current through the gold leaf.

The experiments were hastily and roughly made, but are sufficiently accurate, it is thought, to determine the law of variation above mentioned, as well as the order of magnitude of the current through the Thomson galvanometer compared with the current through the gold leaf and the intensity of the magnetic field.

The results obtained are as follow:—

unless ...

121

Current through gold leaf strip. C.	Strength of magnetic field. M.	Current through Thomson galvanometer. c.	$\frac{C+M}{c}$
·0616	11420	·0000000232	·303000000000
·0210	11210	085	·329
·0389	11060	135	·319
·0508	7670	147	·312
·0505	5700	104	·326

H is the horizontal intensity of the earth's magnetism = ·19 approximately.

Though the greatest difference in the last column above amounts to about 8 per cent. of the mean quotient, yet it seems to conclude that, with a given form and arrangement of apparatus, the action on the Thomson galvanometer is proportional to the product of the magnetic force by the current through the gold leaf. This is not the same as saying that the effect on the Thomson galvanometer is, under all circumstances, proportional to the current which is passing between the poles of the magnet. If a strip of copper, of the same length and breadth as the gold leaf, but 1 mm. in thickness, is substituted for the latter, the galvanometer fails to detect any current arising from the action of the magnet except an induction current at the moment of making or breaking the magnet circuit. It has been stated above that, in the experiments thus far tried, the current apparently tends to move, without actually moving, toward the side of the conductor. I have in mind a form of apparatus which will, I think, allow the current to follow this tendency, and move across the lines of magnetic force. If this experiment succeeds, one or two others immediately suggest themselves.

To make a more complete and accurate study of the phenomenon described in the preceding pages, availing myself of the advice and assistance of Prof. Rowland, will probably occupy me for some months to come.

It is, perhaps, allowable to speak of the action of the magnet as setting up in a strip of gold leaf a new electromotive force at right angles to the primary electromotive force.

This new electromotive force cannot, under ordinary conditions, manifest itself, the circuit in which it might work being incomplete. When the circuit is completed by means of the Thomson galvanometer, a current flows.

The actual current through this galvanometer depends, of course, upon the resistance of the galvanometer and its connections, as well as upon the distance between the two points of the gold leaf at which the ends of the wires from the galvanometer are applied. We cannot, therefore, take the ratio of C and c above as the ratio of the primary and the transverse electromotive forces just mentioned.

If we represent by E' the difference of potential of two points a centimetre apart on the transverse diameter of the strip of gold leaf, and by E the difference of potential of two points a centimetre apart on the longitudinal diameter of the same, a rough and hasty calculation for the experiments already made shows the ratio $\frac{E}{E'}$ to have varied from about 3,000 to about 6,500. The transverse electromotive force E' seems to be, under ordinary circumstances, proportional to M v, where M is the intensity of the magnetic field, and v is the *velocity* of the electricity in the gold leaf. Writing for v the equivalent expression $\frac{C}{s}$, where C is the primary current through a strip of the gold leaf 1 cm. wide, and s is the area of section of the same, we have $E' \propto \frac{MC}{s}$.

DETERMINATION OF CHEMICAL AFFINITY IN TERMS OF ELECTROMOTIVE FORCE.

Electrician June 17 1880

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is stated, p. 189, in *The Electrician* of the 6th inst., that Dr. C. W. Wright read before the Physical Society an "important paper" on this subject. It is also stated that he gave a history of the subject, but not having, as yet, seen the paper, I do not know whether what I am about to say found its place in that history. At all events, I feel it is only due to myself to call the attention of Dr. Wright and others to the fact that this matter was fully worked out by myself in a series of articles which appeared in that widely circulated scientific paper, the *English Mechanic*, in 1871, and which formed the chapter on "Electromotive Force" in my book "Electricity; Its Theory, Sources, and Applications," published in 1875, and itself pretty widely circulated, seeing that 1,700 copies have passed into the hands of the public.

I believe I may claim as my own the definite idea of the actual identity of chemical affinity and electromotive force, and the possibility of definitely expressing the former in the easily ascertained terms of the latter, and I gave the means of doing this and the means of converting one into the other either from experimentally measured electromotive forces, or from experimentally measured chemical forces (such as the heat of combustion). General ideas had been previously expressed by many as to these relations, such as between the forces of batteries and the oxidations, &c., effected therein; but I showed the definite connection, and proposed a unit of conversion, the equi-volt, which in some of its possible forms, would be a perfect unit for all forces and forms of energy. I feel some interest in this, and so claim my rights in the matter, because I have felt that it effectually settles the whole dispute as to the chemical and contact theories, and puts the latter in the famous condition of Humpty Dumpty, beyond the repairing powers of all the mathematicians, and all their cabalistic formulæ.

Dr. Wright has experimented with the decomposition of water (so called), and brings out the force as 1·5038 volts. I gave it, in the places mentioned and p. 222 of my book, as 1·464. Dr. Wright considers that, from his determination, certain corrections require to be made in Joule's equivalent, and compares the values arrived at by different experimental processes. I should suggest that no experimental results, when dependent upon many varying conditions, all subject to error, can be compared in value with those arrived at from sound theoretical considerations. The actual equivalent is attainable from the ratio of the heats of constant volume and pressure of gases, and from the transmission of sound in different densities of air, more correctly than from any experiments specially devised for the purpose. As to the difference between my value for water and that of Dr. Wright, it seems very doubtful if either is really correct. My own was avowedly an approximation based upon the measurement by Favre of the heat of combustion of hydrogen, and subject to other probable corrections; but it appears to me that Dr. Wright's value is too high; that his determination of the electromotive force includes that absorbed in the resistance of his voltameter as well as that represented in the work of decomposition.

While in the act of reclamation, I may also remark that in the No. of February 28th there is recorded a paper sent to the Society of Telegraphic Engineers, on the 25th, by Mr. J. B. Stearns, on some defects in differential galvanometers and the possible remedies. Every one of those matters is mentioned p. 135 of my book. But that is nothing.

J. T. SPRAGUE.

this point in his description in the *Bot. Mag.*, and it was for the further investigation of the case that I raised a plant in my garden.

The flowers grow on long peduncles, which generally have a horizontal position, projecting some five or six inches from the mass of the foliage. When the calyx opens, the filaments as well as the style are irregularly twisted; but in about two or three days all become straight. The style hangs obliquely downwards; the filaments all bend sideways, the bend being inside the tube of the corolla, a little over the hairs at their base. There is often a distance of 15 centimetres between the anthers of either side. About 5 or 6 o'clock p.m. the anthers burst, and soon after the style rises and assumes a central position, so that there is a distance of about 10 centimetres between the stigmata and any of the anthers. *Only then* is nectar being secreted by the glandular disk round the base of the ovary, but so copiously that by means of a small pipette I obtained from each flower a mean quantity of 0·14 cubic centimetres. This nectar is completely transparent, very sweet, and slightly mucilaginous. It contained a kind of gum which is precipitated by absolute alcohol. *The nectar appears therefore when the anthers have done their work;* even an hour before their rupture no trace of it is to be found. The nectar-cavity in the tube of the corolla is completely shut up by the numerous spreading hairs at the base of the filaments, so that an outflow is impossible. The grains of pollen are very large (0·2 millim. in diameter) and of the same structure as in *Cobæa scandens.* They are covered by a glutinous layer, and are heavier than water.

Several weeks passed at first before I witnessed the manner of fertilisation. The stigmata were every morning carefully examined, but no pollen could be discovered on them. The filaments twisted back again and got somewhat frizzled, after one single night's expansion. About noon the corolla drops off, separating from close to the glandular ring, and then slipping down over the style, which, by this time, is again in a relaxed hanging position. There is always some nectar in the tube of the corolla after its separation, but none remains in the calyx round the ovary, nor does its secretion continue.

These facts show clearly that the fertilisation must take place in the same night after the bursting of the anthers, and it was but natural to suppose that it was effected by nocturnal moths. It would appear, furthermore, that *the nectar is not of any direct advantage to the plant*, as Mr. G. Bonnier emphatically affirms (*Annales des Sci. Nat. Bot.*, sér. vi. vol. viii. p. 206), because of its being produced and lost in all flowers, fertilised or not, in the same way.

As soon as the number of flowers increased (on some evenings twenty to twenty-five had their anthers opened), I found every morning most of them with pollen on the stigmata, and keeping a close watch, I discovered that the plant was visited by several large Sphingidæ belonging to the genera *Chaerocampa*, *Diludia*, and *Amphonyx*. I observed altogether four visits of an Amphonyx, three of a Chaerocampa, and one of a Diludia. All of them proceeded in the same manner. Holding the body close over the style, they dipped their spiral tongues into the tube of the corolla, beating all the while the anthers so violently with the tips of the fore-wings that they dangled about with great velocity in every direction. The grains of pollen being covered by a sticky substance, many of them adhered to the wings. I have caught an Amphonyx which, after having visited six flowers consecutively, had the tips of the fore-wings almost yellow with pollen. When leaving a flower for another one, some of this pollen is even lost on the foliage, but by the time the insect takes its central position before the flower the stigmata are likewise touched by the wings, and thus some pollen is left on them. Some flowers remain without being fertilised, especially in places where the moths cannot reach them easily. All flowers fertilised in this manner set fruit very soon; but no flower gave a fruit without having its stigmata pollenised by crossing.

Self-fertilisation is therefore excluded, and this is further proved by the following experiments:—Twelve flowers were artificially fertilised by their own pollen and afterwards protected by muslin bags; only in one case was a fruit obtained; but I am not quite sure whether there did not come some foreign pollen on the stigmata of this flower. Cross-fertilisation was likewise tried in twelve flowers, nine being experimented on in the same evening after the opening of the anthers, and three the next morning. All the former are now with fruit; the latter remained sterile. This fact shows how very short is the period of possible fertilisation.

Flowers visited by nocturnal moths are as a rule either large and of white colour, or have a strong smell; but in our *Cobæa* the former is certainly not the case, and my olfactory nerves at least cannot discover any smell. But it is well known that insects, especially Lepidoptera, are in this respect of a really wonderful keenness, which enables them to track a scent absolutely imperceptible to man.

As I shall have a considerable crop of Cobæa-seeds, I can offer some to any botanists who should wish to grow the plant.

A. ERNST

Caracas, April 4

P.S.—As soon as the corolla has fallen off, the peduncle withdraws slowly amongst the dense foliage, where the fruit develops, protected from all kinds of injury.

EXPERIMENTAL RESEARCHES IN ELECTRICITY[1]

Part III.—*Tube-Potential; Potential at a Constant Distance and Various Pressures; Nature and Phenomena of the Electric Arc.*

MESSRS. De La Rue and Müller, in the third part of their researches on the electric discharge, commence by describing a series of experiments to determine the potential necessary to produce a discharge in a tube, exhausted gradually more and more while using a constant number of cells in all the experiments. In consequence of the life of the battery becoming so much exhausted by the method employed the experiments were confined to one gaseous medium, namely, hydrogen. Since the completion, however, of the measurements described in the paper the authors have found two other more convenient methods for determining the tube-potential, which do not exhaust the battery injuriously; these are described in an appendix. The tube, 162, employed was 33 inches long and 2 inches in diameter, the distance between the ring and straight wire terminals being 29·75 inches; the battery consisted of 11,000 cells. The discharge took place when the pressure was reduced to 35·5 mm., 46,710 M (millionths of an atmosphere), and the exhaustion was afterwards continued gradually until it fell to 0·0065 mm., 8·6 M. In commencing each set of experiments the deflection of a tangent-galvanometer was observed when the battery was short-circuited. By a table previously calculated the value of the deflection in ohms of resistance per cell could be read off; this, multiplied by 11,000, gave the total resistance of the battery; the tube was then connected with the terminals and the galvanometer again observed; this gave a less deflection and indicated a greater resistance, which, multiplied by 11,000, gave the total resistance of the tube and battery: by subtracting the resistance of the battery the resistance of the tube was ascertained. Calling the total resistance R, the tube resistance r, the tube-potential V, $V = \frac{r \times 11{,}000}{R}$. The tube-potential requisite to produce a discharge, with a pressure of 46,710 M, was found to be 10,250 cells; this gradually fell until

[1] "Experimental Researches on the Electric Discharge with the Chloride of Silver Battery," by Warren De La Rue, M.A., D.C.L., F.R.S., and Hugo W. Müller, Ph.D., F.R.S. (*Phil. Trans.*, vol. clxxi. p. 65).

124

centre of gravity had been lowered with each change: "And the conclusion, therefore, at which we have arrived is that, if she lurched and rolled very deeply when fitted as a ship of war, it may fairly be presumed that, but for the presence of the bilge keels, she would have lurched and rolled more deeply as a training ship, still more so on the second cruise, and most of all on her last cruise."

After giving the opinion of Mr. John, who had been requested by the Committee to make an independent series of investigations as to the vessel's stability, that "it was by no means improbable that she would capsize, if caught in a squall of wind unless skilfully handled," and stating that Mr. Barnaby appeared to share Mr. John's preference for a design with less beam and more ballast, the Committee complete this section of their report with the following remarkable paragraph:

"What we are required to say is, whether the Atalanta when she left England in November, 1879, was a stable ship; and the conclusion to which we have come, after a full consideration of all the facts of the case, is that she was on the whole a very stable ship except at large angles of heel; that she was more stable than when first commissioned as a training ship; and much more so than in her previous commissions as a man-of-war."

It is little to be wondered at that the press and the public generally have seized the words "except at large angles of heel" as giving a clue to the whole mischief. Herein to our minds lies an entire confirmation of the views put forward by Mr. John. With a ship carrying a huge spread of canvas, as the Atalanta did, for her size and weight, and lurching heavily and deeply, as is now beyond question, and thus reaching large angles of heel frequently, surely it was at these large angles that she should have been abundantly supplied with stability.

The Committee further say under the head of seaworthiness, that if the Atalanta had been thrown on her beam-ends she would have sunk; and that to have increased her ballast sufficiently to have given her a good righting moment when on her beam-ends, would have been attended with other elements of danger, such as excessive labouring, and a consequent tendency to carry away the masts, which would also endanger her safety. It has been remarked by some of our contemporaries, that it must have been difficult to know what to do with her. Mr. John, in his evidence, stated that he thought her "a type of vessel which it is very difficult to make easy at sea, and very easy to make unsafe." Few will now, we think, be disposed to question this description of her, but still fewer will think she was ever fit for a training ship, to cruise about with 300 young sailors on board. On the whole the impression left by the Committee's report is, that they in effect accepted the views laid before them by Mr. John, which is substantially contained in the following extract from his first day's published evidence:

"Under all these circumstances it appears to me that the Atalanta as equipped for sea on her last cruise, combined an apparent stiffness under her canvas at moderate angles of heel likely to be misleading when combined with a deficiency of stability at large angles for a vessel so heavily sparred in proportion to her displacement. This, combined with the facts recorded as to her deep rolling and lurching, renders it in my opinion by no means improbable that she was capsized in a squall of wind, which might easily have happened if the vessel was otherwise than very skilfully handled."

CHEMICAL AFFINITY AND ELECTROMOTIVE FORCE.

An important paper giving the latest results of his exhaustive research to determine the value of chemical affinity in terms of electromotive force was read at a recent meeting of the Physical Society by Dr. C. R. Alder Wright, lecturer on chemistry and physics at St. Mary's Hospital. In the present article we propose to give the leading and most practical conclusions at which the author has arrived.

Dr. Wright began by considering the true value of the extant British Association unit of resistance, or ohm of electricians, and from a consideration of the values obtained by different experimenters such as Weber, Kohlrausch, and Rowland, he concludes that the true value of the ohm lies between 1 and 1.005 earth quadrants per second, and therefore that until fresh determinations are made, the existing British Association units may reasonably be taken as correct. It follows also that the electromotive force of a new-made Clark's standard element is 0.457 volts, without correction for error in the British Association unit. The qualification new-made is needful, for according to Dr. Wright's experience of these cells, their electromotive force diminishes with age. When carefully prepared they will keep constant for three or four months, but after that the electromotive force begins to decline by a slight percentage, say one or two per cent. in two years. This declension is accelerated or occasioned by air within the cell, and the directions given to seal the mouth of the cell with paraffine wax are hardly sufficient to keep out the air, for the wax cracks at the edges. A better plan is to hermetically seal the orifice of the cell.

By comparing in the same way the different values got for J, or Joule's mechanical equivalent of heat by Joule himself, H. F. Weber, Hirn, Violle, and Wright and Rennie, Dr. Wright finds that if the British Association unit is taken as exactly one earth quadrant per second, then J is 42×10^6 centimetre-gramme-second units, with a probable error of less than one per cent. too great or too small. Joule's values obtained from experiments on the friction of water in 1850 and 1878, namely, 41.57×10^6 and 41.54×10^6 respectively, are probably below the truth.

It is then shown by Dr. Wright that in an electrolytic cell the total work done is that performed in breaking up the electrolyte into the "nascent" products of electrolysis, together with that due to the resistance, R, of the fluid, which is indicated by the expression $C^2 R t$, where C is the strength of current passing, and t is the time it passes. So that by determining the total work by the formula $W = E Q$ (where E is the electromotive force or difference of potential between the electrodes, and Q is the quantity of electricity that passes, or in other words $C t$), and subtracting from it the work of overcoming the fluid resistance $C^2 R t$, there is left the work done in breaking up the compound into the "nascent" products of electrolysis, or $(E - C R) Q$. The quantity $E - C R$ is the counter electromotive force set up during electrolysis which is indicated by e in Ohm's formula:

$$C = \frac{\Sigma(E) - e}{\Sigma(R)},$$

where $\Sigma(E)$ is the sum of the electromotive forces other than the counter electromotive force, and $\Sigma(R)$ is the sum of the resistances in circuit. Hence by electrical measurements the work done in breaking up an electrolyte into its "nascent" products is easily ascertainable; and it ordinarily exceeds the work done in breaking up the electrolyte into its final products.

After discussing the results of previous observers, Dr. Wright propounded the important theorem founded on his own measurements, that the first action of the current is to break up the electrolyte into "nascent" forms which would evolve heat in becoming transformed into the ordinary forms of the bodies produced by decomposition. However, the attractive action of the surfaces of the electrodes employed causes a variable fraction of the products to be evolved not in the nascent state, but in the ordinary condition or nearly so, if solid, and in the form of quasi-liquefied substances if normally gaseous (such as oxygen and hydrogen), thus necessitating a less expenditure of work than would otherwise be requisite to bring about decomposition. Similarly if the electrodes are oxidisable, or if substances which are chemically acted on by the nascent products should be dissolved in the fluid electrolysed or should adhere to the electrodes, or if other analogous physical or chemical changes take place, the energy thus gained is subtracted from that otherwise requisite to be expended to produce electrolysis. The "nascent" products here spoken of are perhaps the ultimate atoms which compose the ordinary molecules of a substance and which in clashing together again to form the molecule give out heat. This theorem indicates the value of e to be given by the series:

$$e = E_1 + \{(1-n_1) H_1 - n_1 h_1 + (1-n_2) H_2 + n_2 h_2 - \Sigma(H)\} \times J,$$

where E_1 is the electromotive force representing the work done in the breaking up of the electrolyte into the final products; n_1 and n_2 the fractions of the total ions at the positive and negative electrodes, which are not evolved in the nascent form; H_1 and H_2 the heats of transformation of the nascent ions into the final products; h_1 and h_2 the heats of condensation of the evolved gases (when the final products are gaseous) to the quasi-liquefied forms of these substances; and $\Sigma(H)$ the algebraic sum of the heat evolved by the action of the ions on the electrodes, &c., including the electromotive force due to the formation of liquids of different densities round the two electrodes respectively. It is further shown by Dr. Wright that this formula includes and accounts for a large number of observed facts in electrolysis.

For instance, the formula accounts for the decline of the polarisation of the electrodes of a voltameter as time elapses after the breaking of the circuit, and the nature of the curves expressing the rate of fall. It predicts that the rate will be greater in water containing dissolved air, than in water free from air, and greater, *cæteris paribus*, with smaller electrodes than with larger ones. These results are verified by experiment. It also indicates that the electromotive force of a Grove's gas battery composed of hydrogen and oxygen must be between 0 and 1.50 volts, and must be subject to great variations under certain conditions, a result which is found to be the case. The phenomenon of so-called "condensation" of voltameters is in strict conformity with the formula, which also accounts for the observation that under certain conditions water may be electrolysed with a visible evolution of either oxygen or hydrogen, or both, by a battery of less electromotive force than 1.5 volts.

A more important practical deduction, however, is that the value of e increases with the strength of the current, though at a less rapid rate; and hence it follows that the electromotive force of a voltaic couple in which hydrogen escapes or a metal is deposited is not constant but diminishes as the generated current increases. This deduction may be experimentally verified on Daniell's, Grove's, and other cells. One result is that Ohm's method of determining the electromotive force of batteries and their internal resistance by means of two or more currents of different strength produced by the same battery, are more or less erroneous, for in these methods it is assumed that the electromotive force of the testing battery yielding the current, remains practically constant. In the case of a Daniell cell the variation of electromotive force with the strength of current given by the cell is sometimes as much as 10 per cent. It is not easy to see how the internal resistance of a battery can be measured without employing at least two currents of different strength. Indeed, if we remember rightly, Dr. O. J. Lodge has endeavoured to show that it is theoretically impossible; but we have Dr. Wright's assurance that it can be done by two methods based on polarisation, and employing only one strength of current. Probably Dr. Wright will publish them before long, and enable electricians to put them into use.

In the course of his laborious experiments Dr. Dr. Wright has made many determinations of the quantity of oxygen evolved by electrolysis in different periods of time by very minute currents, and they invariably show that the law of Faraday, to the effect that there is no conduction without electrolysis, is always observed.

NORTHERN IRON TRADE IN 1880.

In no recent year have there been the fluctuations in the iron trade of the north that have marked the course of the year 1880. These fluctuations have been chiefly in the value of iron—the extent of the trade as measured by the production having been increased with some steadiness, and this not in one branch alone but in most. When the year began, prices were rising rapidly under the stimulus of the demand from the United States, and though that demand collapsed by the middle of the year, and prices returned to their old level, yet the result, in an increased and increasing production of crude iron, and of several kinds of manufactured iron, has remained, so that at the close of the year the output is much larger than at its commencement, and is far above that of the average of recent years. At the beginning of 1880 the price of Cleveland pig iron was based on a standard of 50s. per ton; it rose rapidly to 63s. per ton in the month of March, and it receded as quickly to 39s. per ton by June, since which it has fluctuated a shilling or two up and down. There has been no such fluctuation in the extent of the output. At the beginning of the year there were 99 of the 105 blast furnaces in the Cleveland and Durham district in operation,—and that number has been steadily increased until there

ON THE DISRUPTIVE DISCHARGE OF ELECTRICITY.

BY ALEX. MACFARLANE, D.SC., AND P. M. PLAYFAIR, M.A.

During the months of November and December of this Session we have investigated certain questions suggested by the results already communicated to the Society.

Difference of Potential required to pass a spark between (1) two equal spherical balls at different distances, (2) a plate and ball at different distances, and (3) a plate and point at different distances.

A series of observations was taken for each of these, and on three successive days, without altering the arrangement of the apparatus or the charge of the electrometer. The couple of small Leyden jars were attached to the conductors of the Holtz machine, as we had previously found that it was impossible to observe the discharge between a plate and point with any degree of accuracy when the capacity was small.

Two balls, each of ¾ inch diameter.—The series of observations for the two balls is a more minute and extended investigation of a problem we took up and solved approximately before. We have observed more minutely the values of the readings at the smaller distances, and also noted the cause of the irregularity at the ends. We found that at 80 mm. small violet sparks began to pass before the principal white spark, and that the reading was then more ambiguous than for smaller distances. Escape from the conductor was first noticed at 120 mm.*

Plate and Ball.—We employed a tin plate 8 inches diameter, and one of the brass balls used in the previous experiment. The curve obtained is not very different from that for the two balls; it is somewhat more circular. Small sparks passing before the large one were observed to begin at a shorter distance than in the previous case. Another irregularity at the end was due to the passing of two large sparks. Finally, the electricity began to escape from the insulated wires.

Plate and Point.—The plate used was the tin plate of the previous experiment; the point was conical and of brass. From 1 to 5 mm. the discharge was in the form of a white spark; for higher distances nothing was visible excepting a glow at the point. The series was continued up to 200 mm., as there was no difficulty due to escape of the electricity into the air.

Discharge through a Solid Dielectric.—We obtained, by favour of Mr. Calderwood, of Addiewell Chemical Works, a quantity of a pure solid paraffin of low melting point. The plate electrodes were separated to a distance of ¼ inch inside a glass vessel, the liquefied paraffin poured in so as to cover the plates completely, and then allowed to solidify for twenty-four hours. When the plate electrodes were charged the first spark which passed was large, and illuminated the whole of the paraffin, but the succeeding discharges were much smaller, and of equal amount. The first spark produced a deflection 3·6 times as great as the succeeding sparks. When the plate of paraffin was examined afterwards it was found to be perforated in a zigzag manner, the hole being surrounded by char. We found that—

Electric Strengths.

Air	1
Paraffin when solid	5
Paraffin when liquid	2·5

Thus the electric strength of this substance when in the solid state is, to its electric strength when in the liquid state, as 2 to 1.

As an instance of how these experiments may be made directly useful, I may mention that we obtained two samples of liquid paraffin from Mr. Calderwood to compare their electric strength. We found the ratio to be 1·8. It is, however, extremely difficult to effect the comparison unless we have a considerable quantity of each specimen. It is best to have a dish of the above form, where we can have broad plates, the lower one slightly raised above the glass bottom, and the upper one well immersed in the liquid. The former of these conditions helps to prevent solid particles getting in between the plates, and the latter prevents the rising of the liquid up the stem, and consequent splashing about of liquid particles.

Discharge through Paraffin Vapour.—We put the discharging vessel, with a quantity of one of the pure liquid paraffins, inside the receiver of an air-pump, exhausted the air, and allowed the paraffin vapour to accumulate. When the barometer-gauge indicated 50 mm. pressure, the distance being ¼ inch, we took sparks through the vapour. The spark was of a broad section, green at either end, but of a deep violet between. When a quantity of air was let in white jagged sparks were observed in the midst of the coloured spark. From the readings obtained at 50 mm. pressure we infer that this paraffin vapour is 1·7 times as strong as air.—*Proceedings Royal Society of Edinburgh.*

Scientif. Amer. Aug. 20 1881. 1

A Large Electro-Magnet.

MM. Von Feilitzsch and W. Holtz have recently made, for the University of Greifswalde, an electro-magnet of enormous dimensions. The price of a bar of iron made in one single piece would have been too expensive, while, on the other hand, in a system formed of several pieces poles become developed at the contacts. The electro-magnet was, therefore, constructed of 28 plates of iron, 7 millimeters thick, bent into a horseshoe shape, and of a size such that their combination forms a cylinder 105 millimeters in diameter. These plates are varnished, in order to avoid the formation of extra currents; they are connected together by iron bands, and so arranged as to form a cylinder of uniform diameter. The total height is 125 centimeters, the distance between the poles 500 millimeters; the total weight 628 kilogrammes. The magnetizing helix is composed of 100 kilogrammes of plates of copper, forming 15 layers, insulated from one another by gutta percha.

Outside there are 175 kilogrammes of wire, 2 millimeters thick, forming 5 double layers of wire, and the extremities of the different parts of the circuit communicate with terminals fixed on insulated columns, which allow of any required connections being made. The poles are topped with two plates, 33 millimeters thick, which can be set at any required distance apart, and are capable of carrying various accessories. A movable plate, placed between the two branches, can be placed at any convenient height for the experiments. With this apparatus, excited by 50 small Grove cells, it was possible to melt in two minutes 40 grammes of Wood's metal by Foucault's experiment, and if the poles were set close, the resistance stopped the movement in spite of the tension of the driving band. It is very easy to show the rotation of the plane of polarization in heavy glass, when the latter is traversed by a ray of light, etc. In this apparatus, as has been pointed out, the bar of iron weighs 628 kilogrammes, and the wire 275 kilogrammes, while in the one constructed by Plücker, and which was the largest existing, the weights were only 84 and 35 kilogrammes respectively.—*Les Mondes.*

ELECTRO-DEPOSITION OF BISMUTH.—A series of experiments with various solutions of this metal has recently been carried out in the laboratory of Mr. D. G. FitzGerald at Brixton. Sesquioxide of bismuth dissolved in a hot solution of the double tartrate of soda and potash (Rochelle salt) was found to give excellent results at a temperature of about 160° Fah. The anode should be considerably larger than the cathode or article to be plated, and the electromotive force should be between one and two volts. A perfectly adherent deposit of silvery lustre, but of a darker colour than silver, and not liable to tarnish, may readily be obtained on iron or steel, copper and brass. Mr L. A. Davies, who, as pupil-assistant in the above laboratory, carried out most of the experiments in the question, has, since he resigned that position, written to a contemporary to state that a solution of the ammonio-citrate of bismuth, as well as the solution above-mentioned, possesses all the practical requisites for the successful deposition of this metal. English Mechanic Dec 26 1879

GALVANIC CONDUCTION OF METALLIC ALLOYS.

ACCORDING to Obach's observations, alloys of lead and tin, potassium and sodium, and sodium-amalgam, or alloys of proper metals, conduct the electric current like conductors of the first-class without being decomposed. Now, since, on the other hand, combinations of metals with non-metallic substances are mostly electrolysed, the question remained how combinations of metals with half-metallic elements, such as arsenic, antimony, bismuth, or tellurium would behave. In order to answer this question Herr Elsässer has recently (*Ann. der Physik*) tried the alloy of some metals with antimony and bismuth and by the following method:—

Into one end of a 16ctm. long tube of difficultly-fusible glass, about 1ctm. in internal diameter, a piece of gas-carbon was fixed as electrode. The tube was then fastened vertically and filled with the alloy to be examined. This having been brought into fusion, the other electrode, also of gas-carbon, was introduced into the upper end of the tube. The carbons were at first connected for a long time with the galvanometer, in order to observe any thermo-current that might arise, and then the current from a battery of six large Bunsen elements was so passed through the alloy that the heavier metal must be precipitated at the lower part of the tube. From time to time the electrodes were connected with the galvanometer in order to be able to observe a polarisation current. After the action of the battery-current had continued 4 to 6 hours, the alloy was cooled, the cooled bar taken out of the tube, and pieces about 1ctm. in length taken off the ends and analysed. Herr Elsässer had previously examined whether the alloys, in being fused without a current, remained homogeneous, having fused them in a vertical tube 4 to 5 hours, and determined the specific gravity at the ends. With exception of the antimony-lead alloys they were all available, these five, viz., antimony-zinc, antimony-copper, antimony-tin, antimony-silver, bismuth-lead, and on these the experiments were made.

The result was that none of these alloys was decomposed by the current—the composition at both electrodes was always the same. In the case of antimony-zinc, indeed, a polarisation-current was observed, which was possibly due (the author thinks) to the fact that the antimony-oxide produced at the surface of the alloy was again decomposed.

The selection of alloys for this research was limited to those above-mentioned because many metals give too difficultly-fusible alloys or one too easily oxidised. Arsenic, in place of antimony, gave alloys very difficult to fuse, and out of which the arsenic, in fusion, was volatilised.

"None of the alloys examined by Obach and Lyne," says Herr Elsässer, "were decomposed. Since antimony is, with the exception of arsenic and tellurium, the most electro-negative of all the half-metals, it can hardly be doubted that the alloys of the above-specified positive metals and of positive metals generally, with elements which are less negative than antimony, would also not be decomposed.

"Now, the transition from these compound conductors of the first-class to those of the second, the electrolytes, is evidently not a sudden one. There are between these two groups materials which, at a low temperature, conduct without decomposition, but at a higher, and partly before melting, are electrolysed—*e.g.*, copper and silver sulphide. The sulphides of lead, nickel, iron, bismuth, tin, and antimony behave similarly. These substances share with conductors of the second-class, the peculiarity that their conductivity increases with rising temperature, and so with increased mobility of their particles.

"The same peculiar behaviour characterises a large number of other compounds, which it has not hitherto been found possible to electrolyse, probably only because they are so difficult to liquefy. Such compounds are tin-oxide, iron-oxide, and chrome-oxide. These, therefore, probably belong to this same middle class of compounds which form the transition from the compound conductors of the first-class to electrolytes, while the electrolytes proper do not conduct without being decomposed. To the latter belong especially the haloid compounds of the metals, which are not decomposed in the solid state, because they are mostly insulators. As soon as they begin to conduct, that is, when they are fused, they are decomposed. Some oxygen compounds, also the oxides of lead, antimony, and bismuth and molybdic, vanadic and chromic acids behave thus.

"Lastly, there seems to be still a fourth class of compounds, which in general do not conduct, either with or without decomposition. Apart from this latter group, and considering the compounds which can form a positive element with other elements, ranked according to the position of these elements in the electro-chemical series, then passing in such a series from the positive to the negative side, we first meet with conductors of the first-class, then middle members, which at a lower temperature conduct metallically, at a higher electrolytically, and, lastly, at the negative end, only electrolytes.

"It would be useful for the characterisation of the elements if we could determine, for each of them, in which of its combinations the electrolytic conductivity begins. This is possible now for some of them. The compounds of copper and silver with sulphur permit of being decomposed at a comparatively low temperature, whereas their combinations with antimony and selenium are no longer decomposable. It is probable that their tellurium combinations also behave like conductors of the first class. Accordingly for silver and copper the electrolytic limit would seem to be at sulphur.

"The sulphur compounds of tin, lead, and zinc behave like conductors of the second class. Their antimony compounds are no longer decomposed—the electrolytic limit for these metals, therefore, lies between sulphur and antimony.

"The above-mentioned disturbing properties of many compounds, their difficult fusibility and spontaneous decomposition, unfortunately render it difficult and prevent the fixing of this limit for all elements."

THE THEORY OF THE TELEPHONE.

Electrician July 17 1880

An interesting communication bearing on the theory of the telephone has been made to the French Academy of Sciences by MM. Ader and Du Moncel.

Our readers will remember that in 1879 M. Ader constructed a telephone without a diaphragm, the sound being given out by a soft iron wire enclosed in a helix, through which the current passed. The action was explained by M. Du Moncel to longitudinal vibrations in the wire resulting from successive lengthenings and shortenings of the wire under the action of the magnetising helix, it being well known that an iron core is lengthened by magnetisation. M. Du Moncel employed this fact to support his molecular theory of the action of the Bell telephone. Since that time M. Boudet, of Paris, has, by means of his sensitive microphone, succeeded in revealing these changes of length. Moreover, M. Ader himself has investigated the subject very clearly, and, besides measuring the effect in question, has arrived at the important principle that *all bars of a magnetic nature, submitted to a mechanical action, be it compression, torsion, or tension, tend to recover their primitive molecular arrangement under the influence of the current which magnetises them.*

The apparatus employed by M. Ader in his experiments consists of a small straight electro-magnet, having its core formed of an iron wire 0·01 or 0·05 metres long, and one extremity chamfered off. Upon this chamfer acts a long lever, which serves the double purpose of an indicator and exciter of the mechanical action. The lever terminates in an index which moves itself before a graduated scale (in front of which is a lens), and is connected to the magnetic core in a manner differing with the mechanical action to which the latter is submitted.

In the cases where compression and tension are produced, two distinct effects are seen. On allowing the current to flow for several instants continuously, the index is gently displaced, moving up the scale in the former case (compression) and down the scale in the latter case (tension), with a deflection proportional to the intensity of the battery and the time of closure of the current. This effect is evidently due to the dilatation of the core in each case under the influence of the heat developed by the current, for it is obtained with a core of copper. On closing the circuit momentarily the lever rises instantly in both cases, and instantly falls on the current being interrupted. At the same time a "dry" sound can be perceived at each make and break of the current when the ear is applied against the table supporting the apparatus. But the apparatus is so arranged that the displacements indicated in the two cases correspond to two mechanical effects diametrically opposite in character; that is to say, to a lengthening and shortening of the core. It can, therefore, only be due to a molecular action tending to annul the mechanical strain on the core in either case.

In the case of torsion, the index rises always at the moment of making the circuit and falls again at the moment of breaking it, and in a degree corresponding to the force of the mechanical action, as can be determined by a weight sliding on the torsion lever. In this case the thermal effect is not shown at all, since the indicating lever does not change its position by reason of the lengthening or shortening of the magnetic needle. The magnetisation in this case tends, as in the experiments of MM. Guillemin and Coulon, to untwist the wire.

The length by which the core is shortened by closing the circuit momentarily by the current, according to M. Ader's calculation, is less than one ten-millionth of a mètre, or one ten-thousandth of a millimètre. It is greater under the influence of torsion, and less under the influence of tension.

THE THEORY OF THE TELEPHONE.

Electrician July 31 1880

By experiments made at Toulon in 1878, M. Desportes demonstrated that sounds could be determined in a telephone under the influence of a shock produced in a bar magnet, enveloped by a magnetising coil connected to the telephone. This effect has been attributed to induced currents resulting from displacements of the bar inside the bobbin under the influence of the shock. Experiments made by M. Ader since that time have, however, shown that the phenomenon is more complicated, and, by combining several diverse experiments in order to elucidate the question, he has arrived at some interesting results, which have been recently submitted by him to the French Academy.

Firstly, he shows that if proper precautions are taken to avoid all displacement of the magnetic core inside the bobbin connected to the telephone, if, for example, one coils the wire of the bobbin on the core itself, and stiffens the spires in shellac, no sound is obtained on striking the core with a non-magnetic body. On the other hand, the sounds may be perfectly well reproduced by striking the core with a mass of iron. It can also be reproduced if the ends of the coil thus embedded in shellac are loosely wound around the coil in two or three turns.

Again, if we place inside a small ordinary bobbin metallic cores composed of different metals, we find that only the magnetic metals, *deprived of persistent coercitive force*, provoke the telephonic sounds when struck. Thus, a wire of iron or nickel gives very characteristic effects, *whilst a wire of tempered steel, not magnetised*, produces none.

But what is most important is that these effects are the more energetic in proportion as the core is more divided in the interior of the bobbin, and the best results have been obtained when the magnetic wire was composed of ends of iron wire disposed end to end, and being only one millimetre or two millimetres long by one millimetre in diameter.

Under these conditions the telephone was made quite capable of reproducing speech very distinctly. To effect this, all that was necessary was to place under a telephone diaphragm (of about 10 centimetres diameter and $\frac{1}{10}$ millimetres thick, and furnished with a mouthpiece), a small bobbin of fine wire (No. 40) about five millimetres long, filled with the said fragments of iron wire, and to press with a suitable pressure, the external piece, which ought to be longer than the others, against the centre of the diaphragm. In speaking into the mouthpiece then, a series of vibrations are set up which, in producing a series of corresponding shocks, transmit speech in a satisfactory manner without the necessity of any battery.

The preceding apparatus permits further of proving an important fact which only complicates the question. It proves that *the displacement of the magnetic core in the heart of the bobbin does not suffice to reproduce the sounds.* It is necessary that there should be also a *shock*, and even several shocks. This may be demonstrated by soldering to the diaphragm of the apparatus a wire of iron thrust into the helix. Under these conditions the vibrations displace the iron wire, and in presence of the terrestrial magnet there ought to be developed currents capable of reproducing sounds; but none are forthcoming, and to obtain them it is necessary to place on the coil a second core of iron against which the first may produce shocks. In these circumstances the effects produced can be in some sort analysed by the following experiments:—

If we compress a core of iron furnished with a bobbin wound between two pieces of copper pressed between the jaws of a vice, and if the iron core is rivetted upon one of these pieces, we recognise, on suddenly raising under pressure the other piece of copper, that it produces a sound in the telephone, and this sound is doubtless due to the movement of the magnetic molecules which take their normal position of equilibrium. If we reproduce a similar mechanical action upon the core, but in a manner so as to draw instead of compressing it, we still observe a sound at the moment when the bar takes its normal conditions, and it is the same when torsion is exerted on the core. It may therefore be concluded that all mechanical action having for its consequence a disturbance of the molecular equilibrium of a magnetic core developes at the moment when this core suddenly recovers its condition of equilibrium an electric current capable of being felt on the telephone.

4

Electrician July 31, 1880

Heat Theory of the Galvanic Current.—Clausius points out that Helmholtz's contact theory is inadequate, and he chose to elaborate the theory of the Dutch physicist, Buys-Ballot—that at the contact of two metals, the movement of heat itself causes potential differences. Thomson has given a theory of thermo-electric currents, which is complete, if we assume that the Peltier effect will show itself in one and the same metal at different temperatures. Tait has proved the well-known formula of Avenarius, and Edlund has proved the formula of Thomson—that the electromotive force of a thermo-element at the same difference of temperature is proportional to the absolute temperature. In the rational explanation of thermo-electric phenomena there are inconsistencies :—(1) Thomson's careful experiments still leave it doubtful whether we really find Peltier's effects showing itself in one metal; (2) bismuth is positive to antimony, and yet the current flows in the heated junction from bismuth to antimony; (3) Peclet has proved that with increased temperature the contact difference of zinc and gold is unchanged. (1). The author describes how, using weak currents, he gets the result which Thomson obtained using strong currents. (2). The author gives lists of metals placed according to experiments such as those of Volta and according to thermo-electric experiments. He finds by his own experiments the following contact differences with brass, given in percentages of a Daniell;—zinc 80, bismuth 16, antimony 12·5, silver 4, platinum I. 2·0, copper 1, platinum II. 4·0 gold 8. Platinum I. was chemically pure; platinum II. was the metal of commerce. This list, deduced from the author's careful experiments, he says, proves that the results of Volta, Seebeck and others are correct, in spite of the obvious carelessness of their methods. He goes on to show that, for instance, in a bismuth-copper junction, the electromotive force produced in the bismuth itself tending to give a strong current from cold to hot parts of the metal, is actually greater than the contact electromotive force of the two metals; and hence, since there is only a small effect of this kind produced in copper, these metals ought to be differently placed in a contact list and in a thermo-electric list. This is also the reason why we find the neutral points in thermo-electricity. The author gives an experiment bearing out the above explanation. (3) He repeats Peclet's experiment, and gets a result which is in accordance with theory. He, therefore, concludes that potential differences shown on heating are only modifications of those discovered by Volta; and as thermo-electric phenomena are explainable by the laws of thermodynamics he uses to explain Volta's contact differences, heat effects at the junctions. He deduces from this that not merely chains of metals, but chains of metals and liquids should owe their electric currents to heat effects at the junctions; so that we must not explain them by changes in chemical effects. He discusses the case of zinc in sulphate of zinc, where there is an electromotive force of contact, and yet in which there is no chemical action. He describes an experiment showing that the positive electrode in a decomposition cell becomes warmer than the negative. The author describes arrangements by means of which zinc plates were maintained at different temperatures in sulphate of zinc, and copper plates in sulphate of copper, and he finds that the ratio of the electromotive forces of these cells is 1·26. He also finds that the thermal currents between metals and fluids depend, as regard their direction, only on the fluids, and not on the nature of the metals. The author, after declaring that the question—Is the electromotive force of Daniell equal to the sum of—

$$Zn \mid Cu,\ Zn \mid Zn\,So_4,\ Cu \mid Cu\,So_4$$

has not hitherto been taken up, proceeds to describe his experiments proving that this is true. He finds—

$$Zn \mid Zn\,So_4 = 48 \text{ per cent. of a Daniell,}$$
$$Cu \mid Cu\,So_4 = 27{\cdot}4 \quad \text{,,} \quad \text{,,}$$

He then proceeds to consider the well-known statement that the direction of the current in a cell depends on the nature of the chemical effects producible at the junctions, and he shows by the example of a single cell formed of lead and copper in water that the statement is not always true. Thus, according to Favre—

$$Pb\,O - H_2\,O = 27{,}675 - 34{,}462 = -6{,}787 \text{ heat units.}$$
$$Cu\,O - H_2\,O = 21{,}885 - 34{,}462 = -12{,}577 \quad \text{,,}$$

and yet this cell gives a pretty strong current, which, in the fluid, has the direction from lead to copper. The remainder of the paper is devoted to a theory of the voltameter, based on the following principle:—When a certain amount of polarisation is in existence, not the maximum amount, it is as if one of the platinum plates had a number of buttons of zinc partially covering its surface, so that the current from a voltaic cell when it enters the voltameter is in parallel circuit. In one path through the voltameter there is no opposing electromotive force, but by the other there is such an opposing electromotive force, and this latter becomes more and more important as time goes on. He deduces the result—

$$J = \frac{E - \frac{p}{n}}{R + r},$$

Where p is maximum polarisation, E the electromotive force of battery, r resistance of voltameter, R all other resistance of the circuit, J the current, and n a number which depends on the time decreasing from infinity to 1 with a rapidity determined by the current and the area of platinum plates. The author describes many experiments illustrating his theory—refers to Edlund's experiment showing that the heat effects produced in a voltameter are not merely those due to current resistance but also to polarisation—refers to the fact that Favre found the simple cell zinc, sulphate of zinc, platinum, to cool when it produced a current, and shows how other facts of the same kind are explainable on thermodynamic principles.—Abstract of a paper by M. Hoorweg in *Annalen der Physik und Chemie*.—*Jnl. Soc. Tel. Eng.*

THE MECHANICAL ACTION OF LIGHTNING.

Sc. Am. Sup. Aug 14/1880

WITHIN the last few days England has been visited by several thunderstorms of considerable severity, and deaths caused by lightning have taken place in three or four localities. Trees have been rent, animals slain, houses injured, and there is some reason to conclude that the summer of 1880 may become rather remarkable for the manifestations of electric disturbance taking place in Great Britain. Although it is well understood that thunderstorms are always in a certain extent dangerous; and although most buildings, public or private, of abnormal height, are provided with lightning conductors to protect them, very few persons know accurately what lightning is. That portion of the general public which is fairly well informed, holds that a flash of lightning is a discharge of electricity from a cloud to the earth. The country journalist regards it as "a discharge of the electric fluid." The ignorant peasant speaks of a thunderbolt, and believes that an invisible something concealed in a "flash of fire," comes from the sky and slays, or rends. If we turn to text books for information we shall find very little. "Lightning," writes Professor Fleeming Jenkin, "is an enormous electric spark passing between two clouds, or from a cloud to the earth." We shall see in a moment what it is that Professor Jenkin calls a spark, and we shall be able to judge whether the conditions are such that an electric spark and lightning are one and the same thing. But before going further we must ask our readers who may care to peruse this article to think a little for themselves. It is not probable that they can thus find out what a flash of lightning is, and it is certain that we cannot tell them, but we at least show that it is possible to construct a theory concerning the phenomenon which is consistent throughout.

We may start by saying that lightning is unquestionably a form of electrical discharge, and it produces effects in always analogous to those produced by a discharge from a Leyden jar or other reservoir of high tension electricity. It has recently been urged that electricity is a mode of force. It is very difficult, though not impossible, to form a mental conception of a pure force, isolated and apart from matter; but be electricity what it may, it makes its presence known to our senses by its effect on matter; and there is, furthermore, reason to believe that matter which may be invisible or imponderable is first acted on before that kind of matter with which mankind is more or less familiar. Let a Leyden jar—one large enough to hold about two quarts of water will answer very well—be fully charged, and then discharged through a sheet of thick pasteboard. If matters are properly managed a hole may be punched in this way through a thickness of about a quarter of an inch. If this hole be examined it will be found that, although the edges may be singed, it has not been burned through, but punched through. The hole will be very like in its character to those made by a charge of No. 9 shot fired at a distance of twenty yards through a similar sheet of pasteboard. It is very difficult to conceive that such a hole has been made by the passage through the pasteboard of a pure force; all the evidence goes to show that something, that is to say, some form of matter, has gone through the cardboard and made the hole. If a piece of the pasteboard target, with one shot hole only on it, and the piece of card punched by the electric spark, were handed to a man who did not know anything of how the holes were made, he would say of both that something, either a shot or a rather blunt metal instrument, had been driven through the material and left the holes behind. There is, however, this to be noted, that in many cases the hole appears as though it had begun within the substance of the paper, and not at one side or both. It has been laid down that when an explanation of any phenomenon or occurrence is available which satisfies all the conditions, it is unnecessary and illogical to offer theories based on any second hypothesis. The electrically punched hole is just such a hole as would be made by the passage of something material through the paper, and so far we have reason to believe that something material has passed through. Now, if we compare the effects of a Leyden jar spark with those produced by lightning, we find a strict similarity between them. The lightning is different from the Leyden jar spark not in kind but in magnitude. When stone is ground to powder, or a tree split, we are justified in asserting that matter in some form or other came in contact with the stone and powdered it. It is supposed that trees are split by the production of steam from their juices by the heat of the electric discharge; and when lightning strikes sand it often produces curious tubes of fused quartz called fulgurites. But allowing for this, a sufficient number of cases occur in which the effect produced is certainly not due to heat. At first sight these statements will, perhaps, seem to a few of our readers as extremely heterodox. They will say that we have a theory of material thunderbolts, such as the ignorant peasants hold. Our reply is, that there may be thunderbolts and thunderbolts, but that the peasant, according to his lights, has spoken and reasoned wisely. He has assumed that a great hole cannot be dug in the earth unless something of which the soil can take cognizance has operated upon it. We cannot form any conception of a hole being dug in a field by a pure force. Nor can we imagine such a mundane thing as a block of granite reduced to powder save by the impact or influence of something very different from pure force. There may be forms of matter, however, susceptible to the operation of pure forces. We neither assert nor deny that such is the case, but it is more reasonable to suppose that when a stone is shattered or a hole pierced, or an excavation made, it is made by some form of moving matter than by anything else. Lest it should be said that in assuming that the electric spark is a manifestation of matter in motion we are standing alone, we shall support our opinions by the following quotation from Prof. Fleeming Jenkin's "Electricity and Magnetism:" "The distribution of electricity over bodies which have points or angles is such that the electric density becomes very great on these points as it would on a very small sphere, even when the potential is not high. The result is a great repulsion of the electricity for itself, or rather a great repulsion between the neighboring parts of the matter charged with it. We then frequently see *the electrified matter passing off in the condition known as the electric spark.*" Again, in another place he writes: "The electricity has such a repulsion for itself that if it accumulates sufficiently the force becomes great enough to break down the pressure of the air, and *highly electrified particles of the conductor and of air fly off the point. Every electrical spark seen is an illustration of this convection. Lightning is one example.*" The italics are ours. We are apparently justified then in saying that the hole was punched in our card by a volley of missiles dispatched from the surface of the ball of the discharger, and that the mechanical effects of lightning are in like manner possibly due to a volley of missiles discharged from the clouds to the earth. It is more than probable that few of our readers, who are not trained electricians, have before heard or seen the statement, which we have just made. Its truth does not admit of direct demonstration, but it does admit of indirect demonstration.

We may now turn our attention to the nature of the missiles with which we have to do. Apparently there is nothing very alarming about them. A thunderbolt may be a very small thing indeed—let us try to give our readers an idea how small. It is not easy to say what the velocity of a flash of lightning may be; but we have to deal particularly with the fact that particles of matter have to be dispatched with a certain velocity like shot from a gun. Let us assume that this velocity is 50,000 miles per second; it is possibly very much more, but 50,000 miles will suffice. Let us suppose that we have one pound of matter moving at 50,000 miles, or 264,000,000 feet per second. The work stored up in our pound of matter will be found by the formula $\frac{Wv^2}{2g}$, and it amounts to 1,089,000,000 foot-pounds, or over 486,100 foot-tons. It is impossible to convey an adequate conception of the mighty force with which we are dealing. Let us suppose that we have a thunderbolt which weighs one ounce moving at 50,000 miles in a second. It would represent 30,000 foot-tons in round numbers, or a force great enough to lift a great ironclad bodily 3 feet. The one hundredth part of an ounce would have stored in it a capacity for doing work amounting to 300 foot tons. It would lift a rock weighing 3 tons 100 feet. A "thunderbolt" weighing as much as a grain of small shot would be competent to demolish a steeple or to rend an oak.

The mechanical action of lightning, then, may be due to the impact of very minute quantities of matter moving at a prodigious velocity. Their energy is due solely to their velocity, and the comparatively isolated range of the influence of lightning is no doubt attributable to the circumstance that the quantities of matter involved are exceedingly minute, and owe their power entirely to their speed. A cannon ball, moving at comparatively small velocity, may stun, and bruise, and batter, and spread destruction over a wide range; but not so the lightning flash. Just as a bullet, fired through a pane of glass, makes a hole in it, so is the action of lightning confined to beaten tracks and narrow strips of paths. We have, it will be noticed, made no attempt to explain why or how electricity imparts velocity to particles of matter. That no one knows. Nor have we said what form of matter our "thunderbolt" is composed of. Possibly molecules of oxygen or hydrogen from the water in the electrified clouds. Nor have we said anything concerning the charge of electricity which, no doubt, accompanies the matter put in motion, and which, by its inductive effects, may kill men or animals without touching them. Electricity is yet enveloped in a cloud of mystery, rifted here and there, but black as night elsewhere. We have endeavored to show that, according to the best authorities, the electric spark is due to matter cast off from conductors; and we have supplemented this by pointing out that the most insignificant quantity of matter, moving at a sufficiently high velocity, can contain enough energy to account for the mechanical effects produced by lightning. If our readers find inconsistencies in the theory, they must not blame us. The theory, as set forth here, is the legitimate deduction from observed phenomena and the writings of the best authorities on electrical science.—*The Engineer.*

Science, May. 1881.

THE CONSERVATION OF ELECTRICITY.

The following is from the preface to "Elementary Lessons in Electricity and Magnetism," by SILVANUS P. THOMPSON, now in the press.

"The theory of electricity adopted throughout is that electricity, whatever its nature, is *one*, not *two*. That this electricity, whatever it may prove to be, is not *matter*, and *energy*; that it resembles both matter and energy in one respect, however, in that it can neither be created nor destroyed. The doctrine of the *Conservation of Matter*, established a century ago by Lavoisier, teaches us that we can never destroy nor create matter, though we can alter its distribution and its forms and combinations in innumerable ways. The doctrine of the *Conservation of Energy* which has been built up by Helmholtz, Thomson, Joule, and Mayer during the last half century teaches us that we can neither create nor destroy energy, though we may change it from one form to another, causing it to appear as the energy of moving bodies, as the energy of heat, or as the static energy of a body which has been lifted against gravity or some other attracting force into a position whence it can run down, and where it has the potentiality of doing work. So, also, the doctrine of the *Conservation of Electricity*, which now is growing into shape, but here first enunciated under this name, teaches us that we can neither create nor destroy electricity, though we may alter its distribution—may make *more* to appear at one place and *less* at another—may change it from the condition of rest to that of motion, or may cause it to spin round in whirlpools or vortices which themselves can attract or repel other vortices. According to this view all our electrical machines and batteries are merely instruments for altering the distribution of electricity by moving some of it from one place to another, or for causing electricity when heaped up in one place to do work in returning to its former level distribution. Throughout these lessons the attempt has been made to state the facts of the science in language consonant with this view; but rather to lead the young student to this as the result of his study than to insist upon it dogmatically at the outset."

THE ALTERNATING ELECTRIC DISCHARGE.

Electrician Aug 21 1880 10

The alternating discharge apparatus devised by M. Thenard is well adapted to show the shower of electric fire in different gases under various pressures, for the phosphorescent lights, invisible in full day, which illumine the gas placed in the annular space comprised between the two tubes of concentric gas, when analysed with care in the obscurity, always exhibit the character of a shower.

If the phenomenon is very difficult to observe in oxygen, it is, on the contrary, found by MM. Hauteville and Chappuis to be very easily recognised in fluoride of calcium.

When produced at atmospheric pressure in this substance, the spark has the appearance of a homogeneous luminous sheet. The annular space is filled with little luminous globules of a greenish yellow hue in darkness, and a tender rose colour in diffused light, the flame of a candle. In examining the tube by a magnifying glass during discharge, we are struck with the analogy which the phenomenon presents with that described by MM. de Mondesir and Schlosing in their beautiful experiments on "electric butterflies," where the burning of hydrogen in the air gives lights which move like swarms of flies.

The discharge in fluoride of silicon is easiest of all to study if the distances of the electrified surfaces attain several millimetres, because the luminous points, well separated, show that the successive discharges take place under the form of little luminous cylinders joined to small phosphorescent sheets with circular outlines; so that if the two cylinders are concentric, the central tube seems to be plastered on its exterior surface with regular luminous lines, equidistant, and terminated at the other tube, the whole recalling a mop with luminous tags. If the two cylinders are not concentric, the discharge only passes between the nearest walls, allowing the phenomenon to be studied on the edges. The space seems traversed by a shower of fire, as in the apparatus of M. du Moncel.

A diminution of pressure of the fluoride of silicon does not change the general characters of the discharge; but, in withdrawing the tubes of electrified glass, it can be readily proved that each luminous line is swollen at the ends. With low pressures the luminous drops, instead of designing themselves on a black background, seem hid in a violet mist. At the same time their contours loose their definition. A maximum of splendour is seen in the discharges which occur in the plane passing through the observer and the axis of the apparatus. The cylindrical lines, if dilated in rarefied gases, preserve, nevertheless, a lively splendour when the eye looks along them.

For pressures below ·005 mètres the general illumination masks the shower of fire almost completely—the drops seem to be deep in the mist.

Nitrogen is, after fluoride of silicion, the gas which gives the finest rain of fire. At ordinary pressure the globules—of a pale reddish blue—are very small and very close. The phenomenon takes more splendour of colour when we reduce the pressure of nitrogen to what supports the gas in air. We only obtain a luminous sheet of homogeneous appearance at pressures below 0·050 mètres.

Hydrogen exhibits also this form of discharge. At atmospheric pressure the phenomenon in colour is almost identical with what we observe in fluoride of silicon at low pressures.

The same appearances are observable with chlorine. The luminous drops are greenish, and much less brilliant than those of fluoride of silicon. This gas, under ordinary pressure, opposes a very great resistance to the passage of electricity. The electrified surfaces ought to be very near, for if they are at 0·002 mètres, for example, the luminous lines, without having the character of a spark, resemble it in luminous intensity. This mode of discharge is distinguished from the preceding by the small number of luminous lines and the brilliant *aigrettes* which appear on the surface of the walls of the tube, uniting amongst them the successive lines situated sometimes more than a centimetre from each other.

In oxygen the discharge is hardly visible, the gas becomes very slightly luminous, or rather phosphorescent. Nevertheless, in darkness, and by the aid of a magnifying glass, a granulation on the surface of the concentric tubes can be noticed; and, if the gas has not too feeble a tension, the distinct luminous globules can be detected.

The constitution of the milky white lights produced by the alternating discharge in carbonic acid recalls the lights observed in oxygen, but the analysis of them is easier.

These discharges are only silent, in all gases, at feeble pressures. They are silent also in hydrogen at atmospheric pressure. The rain of fire is accompanied in other gases by a rustling sound.

Discharge tubes, such as are constructed by M. Alvergniat, will show the rain of fire under its various aspects in different gases under different pressures.

jour : à quinze mois, il doit peser le double de ce qu'il pesait à cinq mois : soit 14 kilog. En général, un enfant qui s'accroît de moins de 20 grammes par jour doit être considéré comme mal nourri, comme malade ou sur le point de le devenir. Il va sans dire qu'il se présente presque toujours des exceptions à la règle.

Le savant praticien cite, entre autres exemples qui prouvent l'utilité des pesées, le cas suivant communiqué par M. Tarnier : Un enfant bien venant, de neuf à dix mois, allaité par une bonne nourrice, avait depuis sa naissance une croissance régulière. Sans cause appréciable, on vit d'abord le poids de l'enfant cesser d'augmenter, puis, après dix jours d'état stationnaire, on constata une diminution. On incrimina à tort la nourrice. Trois semaines après l'arrêt d'accroissement, il se déclara une méningite à marche rapide qui enleva l'enfant.

Nous ne pouvons suivre dans leur détail les prescriptions très-sages et très-prudentes qu'a résumées M. René Blache dans son travail. Il nous suffit de les avoir signalées aux intéressés, et d'avoir encore une fois insisté sur tout le parti que l'on peut tirer de l'emploi de la balance pour contrôler le développement normal de l'enfant.

H. de P.

LE TOPOPHONE

NOUVEL APPAREIL POUR PERCEVOIR LES SONS

Lorsqu'un navire à vapeur ou à voile navigue par un temps de brouillard intense, il est ordonné par les règlements maritimes de faire jouer le sifflet à vapeur ou sonner la cloche du bord, afin de prévenir les autres bâtiments et de les éloigner de la route suivie. Chaque année les journaux nous apprennent que tels ou tels bâtiments suivant la même route se sont abordés, et qu'un sinistre s'en est suivi. Qui n'a encore présent à l'esprit le terrible abordage du paquebot la *Ville du Havre* par un bâtiment à voile? Mais il arrive souvent que le bruit des vagues, du vent, celui qui se produit sur le bâtiment, ne permet pas de juger exactement d'où vient le bruit de sifflet ou de cloche entendu. Dans ce cas, il peut y avoir rencontre fortuite tout comme si l'on avait négligé de se conformer aux règlements maritimes internationaux.

Le journal suisse : *le Monde de la Science et de l'Industrie*, nous fait connaître aujourd'hui un appareil très-curieux dû à M. Mayer, le *topophone*, destiné à se rendre compte de la direction en quelque sorte topographique d'où vient le son.

Le topophone de M. Mayer consiste en une tige horizontale de bois, disposée de manière à pouvoir se poser en équilibre sur le cou et les épaules, à la manière de ces leviers qui, dans certains pays, servent à porter les seaux d'eau. A chaque extrémité de cette tige-levier est un résonnateur ou appareil destiné à recueillir et à renforcer le son. Ce résonnateur est une caisse en métal dont une paroi est légèrement concave et percée à son centre d'une petite ouverture. A la paroi opposée, également terminée par une ouverture, est adapté un tube de caoutchouc qui vient se terminer à un cornet acoustique placé dans l'oreille. Les deux résonnateurs peuvent glisser sur les bras du levier afin de recevoir la position la plus favorable à la réception du son, et les deux tubes viennent se réunir sur la poitrine dans une même enveloppe, pour de là se bifurquer vers chaque oreille. Tout le système est maintenu en place par un ensemble de ceinture et de courroies.

Lorsque l'officier porteur de cet appareil veut distinguer d'où vient le sifflet ou le son de la cloche que les guetteurs ont perçu, il se tourne dans plusieurs directions,

Fig. 00. — L'officier porteur du topophone.

et suivant qu'il se rapproche ou s'éloigne de celle d'où proviennent les sons, les résonnateurs les répètent avec une intensité plus ou moins grande. On comprend alors que l'officier-observateur étudiant à quel moment le son du résonnateur est plus intense, se rendra compte de la direction d'où provient le son avertisseur et fera route en conséquence. Deux navires pourvus de topophones pouvant se rendre un compte absolument exact de leur position, les accidents par abordages, les plus redoutables sur certaines routes maritimes, notamment celles de New-York, par les bancs de Terre-Neuve, deviendront beaucoup plus rares et peut-être même arriveront à ne plus se produire.

P. L.

EARTH CURRENTS.

Electrician 2/1 1880

Several communications have appeared in our daily contemporaries, referring to aurora, seen by various observers on August 12th. In "Slip" will be found those inserted in *The Times*. Connected possibly with this phenomenon we have accounts of strong earth currents on and about this date. A most interesting statement describing the earth currents on various cable lines, has been sent to us by Mr. H. Saunders, electrician in chief to the Eastern Telegraph Company. The phenomena of earth currents are so universal, so important to science, and so little understood, that we hope some way will be found to accumulate facts, from which data laws may possibly be deduced. Mr. Saunders, speaking of the electrical and magnetic disturbances of the 12th and 13th August says:—

"The earth currents on those days were exceptionally strong and variable, causing great interruption to the traffic over all the English and Continental lines, so much so that the Director of Telegraphs in France gave notice in the papers of the cause of delay to telegrams.

"I have collected the following data as to what was observed on the Eastern Telegraph Company's system and the Eastern and South African Company.

"Between London and Porthcurno, and London and Marseilles, and London and Liverpool, there were very considerable disturbances all day of the 12th, the maximum effects being observed between 11 a.m. and 4 p.m.

"The English Government and the Submarine Company's systems were also affected.

"The system upon which we work most of our lines, which is purposely intended to block earth-current disturbances, prevents them being noticed except when very strong and variable, so that on the cables from Porthcurno to Lisbon and Vigo nothing very unusual was observed; but upon a cable from Lisbon to Vigo, which is undergoing repair, and upon which an instrument is kept in circuit, strong and variable currents were observed on the 12th and 13th, the maximum being between 11 a.m. and noon, the weather being unusually calm and the sky thickly overcast.

"At Gibraltar very strong currents were observed on the cable to Lisbon at 10.45 a.m. of the 11th. On the 12th there were strong currents both on the Lisbon and Villa Real cable, maximum at 11.46 a.m., and currents on both cables during the 13th, but not so strong. Little or no current was noticed on the cable between Gibraltar and Malta on either of the days.

"Malta observed nothing unusual on the cables connected with Gibraltar, Marseilles, and Alexandria, nor did Alexandria observe anything on any of the cables connecting Malta, Cyprus, and Candia. In the Levant there was considerable disturbance on most of the lines. The Otranto Zante cable was violently disturbed between 10 a.m. and 4 p.m. of the 12th, and the Zante-Candia line the whole of the day, rendering working very difficult.

"On the 13th the former section was free, but the latter still slightly disturbed. Candia did not have anything unusual either on the Syra or Alexandria cables. The currents were also very strong upon the cables connecting Syra with Tenedos, and Pera and Tenedos and Salonica, as also on the Turkish lines, both on the 12th and 13th. The currents were not observed on the cable at Cyprus connected with Alexandria, but were on the land lines on both days, strongest on the 13th, and on the Larnaca Limassol section. Nothing exceptional was observed on the cables between Suez, Aden, and Bombay. But, curiously, currents appeared upon the Eastern and South African cables between Zanzibar, Mozambique, Delagoa Bay, and Natal. It is all the more curious that, as a rule, these lines are very free from earth currents.

"This is, of course, a very imperfect record, owing to the fact that cables are dividend-earning machines in the first place, so that when there is trouble on the lines the whole of the efforts of the staff are devoted to getting the traffic through, leaving little time for scientific investigation.

"However, the salient points are sufficiently determined, viz.:—

"1st. The extent of the disturbance extending over Europe, as far as Constantinople, down to the extreme points of the southern coast at Gibraltar and Otranto, but not affecting Malta or Egypt, nor the Red Sea; but turning up again at Zanzibar and along the east coast of Africa.

"2nd. The remarkable coincidence as to the time of maximum effect at different places widely separated.

"These disturbances are generally accompanied by displays of the aurora borealis, and I see from a letter in *The Times* of the 14th that a vivid display was seen from Ilfracombe on the night of the 12th, extending over nearly 40° of the horizon beyond the Welsh coast. The aurora was visible at Suez on October 24th, 1870, and again on Feb. 4th, 1872, when there were great electrical disturbances over all the lines. During the last I measured earth currents equal to 170 Daniell cells upon the Suez and Aden cable. The aurora was preceded in each case by electrical disturbance on the line, and in the present case earth currents had been unusually strong for some days before, although during the actual time of the greatest disturbance on other lines the Suez-Aden section was clear."

ELECTRO-TELEDYNAMICS.

BY PAGET HIGGS, LL.D.

(CONTINUED FROM PAGE 148.)

Electrician Mar 13 1880

For a first consideration of the subject, there will be more interest in approaching it from a point of view whence we can be accompanied by the practical engineer, for it is to him that promoters of the system of electro-teledynamics must bring the details in order that the system may have the full appreciation it merits.

The first question that arises usually in such discussions is—What size and kind of conductor will you use? Before giving a direct answer to this question let us ascertain what current an ordinary telegraph line will carry. And for this purpose we may select, as a most convenient size, an ordinary line-wire of No. 6 American gauge (= ·162 inch diameter) corresponding very closely to No. 8 Birmingham wire gauge (= ·165 inch diameter), and to the French 4 mm. wire. Calculated in C.-G.-S. units from the specific resistance of iron as 9827, this wire would have 2·4 ohms for 1,000 feet, or 12·65 ohms a mile; in practice, however, the resistance would be taken at 3 ohms for 1,000 feet.

There are two points to be determined—How rapidly the wire will become heated by a current? and how rapidly that heat will be emitted into the surrounding atmosphere? It is not at all advisable to push the heating to extreme limits, because this heat not only represents loss of work by loss of current in heating effect, but it decreases the capacity of the line by increasing the electrical resistance. Therefore, we must consider the temperature in the wire as to be not much above that of the surrounding atmosphere. It may seem unnecessary to dwell upon this point, but there appears to have been but little consideration given to it. Sir William Thomson even, in a hasty speech before the Institution of Civil Engineers, when this subject was under discussion in 1878, says: "The most practical way would be to put the wire in the shape of a copper tube. Having a copper tube, with a moderate amount of copper in its sectional area, and a current of water flowing through it, with occasional places to let it off and places to allow water to be admitted for the purpose of cooling, there would be, without any injury to the insulation, a power of carrying heat practically unlimited." One does not always have the good fortune to catch so great a philosopher tripping, but this statement has been so often quoted to me that I am compelled to point out that the heat carried away by the water is work carried away and lost (unless we use the water in our dwelling houses or in some equivalent way). Further, such a loss does not compensate in any equivalent gain; for, calcu-

lating the heating effect as work and as taking place in the circuit proportionally to the resistance of the various parts of the circuit, we cannot afford to lose heat (beyond a necessary quantity) in the motive or line circuit.

It is requisite, then, to determine the emissive rate for the wire in question, and afterwards to ascertain the current that will generate only that quantity of heat the wire can emit under usual atmospheric conditions.

A thousand feet of the wire under consideration—and the consideration of a thousand feet will, for the same current, be the same as for a thousand miles—will have an emissive surface of 38,100 square centimetres. I have determined, by rough experimental means, although with sufficient accuracy for the purpose, the loss of heat from new and from old galvanised iron wire, and the results I have obtained differ, as far as I have carried my experiments, but little from those obtained for copper surfaces as described by Mr. D. M'Farlane in the *Proceedings* of the Royal Society for 1872 (p. 93). It may for all practical purposes be taken, for between 30° and 60°C. differences of temperature of the wire and the surrounding atmosphere, that ·0003 unit of heat is lost per second per square centimetre of surface for each degree of difference of temperature. The surface of the 1,000 feet of wire will, therefore, have an emission of 11·43 units of heat per degree of difference, and assuming the atmosphere at 64°F., or say 18°C., we may take conveniently a difference of 30°C., bringing our wire to a temperature of 48°C., or say 118°F. This will give us a rate of emission (including surface conduction) for heat of 343 units of heat a second; in other words, there is that quantity of heat emitted sufficient in one second to heat 343 grammes of water 1°C.

The specific heat of iron is, nearly enough for our purpose, 0·1—that is, an equal weight of iron would require one-tenth of the heat necessary to raise the same weight of water to a given temperature. As 343 units of heat (gramme-degrees) is represented by 11·43 grammes of water raised 30°C., the same quantity of heat would raise 114·3 grammes of iron to the same temperature.

But in the 1,000 feet of iron wire are 29,750 grammes of metal, therefore there are required 89,313 gramme-degrees to raise this wire to 30°C. above its normal or atmospheric temperature, and to maintain this temperature against the loss of heat by emission and surface conduction.

This wire has a resistance of 3 ohms, and we have to find what current in webers will produce on this resistance the required quantity of heat. We have the well-known simple equation $0·2406\ C^2 R = H$; and having H given as 89,313 and R as 3, we find C = 353 webers.

The conclusion has been arrived at, by a somewhat round-about process it is true, that a common telegraph wire of No. 8 B.W.G. will convey a current of 350 webers with perfect safety and without appreciable heating effect.

A NOTE ON EXNER'S PAPERS ON CONTACT ELECTRICITY.

BY PROFS. W. E. AYRTON AND J. PERRY.

The authors' attention was drawn to Prof. Exner's papers about a year ago by Prof. Fleeming Jenkin, but on reading them it did not seem necessary to answer them. Finding now, however, that they have been translated and reprinted several times, and that they are calculated to mislead, it has been thought well to bring a criticism of them before the society. Starting from Thomson's (or Joule's) well-known theory that the heat of combustion, due to the chemical actions going on in a cell, represents the E.M.F., Exner states that the difference of potential between zinc and its oxide, which he calls 2 E, is measured by the heat due to oxidation of zinc. If, now, a non-oxidisable metal, say platinum, is brought into metallic connection with the zinc there is no difference of potential between the zinc and platinum, the platinum takes part of the charge of the zinc, and the difference of potential between the platinum and the oxide of zinc becomes E. And from this it follows that the difference of potential between two metals in contact in air is measured by half the difference of their heats of combustion in oxygen. To show that his reasoning is correct, Exner has made experiments on three such differences of potential, which agree very remarkably with the theory. The authors first consider Exner's theory, and show that, even if they allowed the first assumption, the reasoning disregards what is known of the laws of electricity, for Exner does not assume a constant difference of potential between zinc and its oxide since this begins at 2 E and ends with E; neither does he assume a constant quantity of electricity in the oxide, for in that case his last difference of potential would depend altogether upon the condensing arrangements employed in the experiments. So that Exner has simply assumed what a casual reader might think he had proved, viz., the above statement as to half the difference of heats of combustion. But if the statement agrees with experiment, Messrs. Ayrton and Perry showed that it might be regarded as a most important empirical law. Now, Professor Hoorweg has shown in a paper in *Wiedemann's Annalen* that Exner's experimental results are in complete disagreement with those of Kohlrausch, Hankel, and Ayrton and Perry, and gives the following table:—

	Kohlrausch.	Hankel.	Exner.	Perry and Ayrton.
Zn | Pt	0·984	0·984	0·881	0·981
Cu | Pt	0·184	0·184	0·367	0·238
Fe | Pt	0·384	0·312	0·704	0·369

So that, although Exner gives as his reason for his making the above experiments, that the results of all experimenters since Kohlrausch's time are isolated and unreliable, it would seem that the consistency of these three series of determinations with each other, and their inconsistency with his new measurements are such as to make us reject his statement even as an empirical law. The authors then take up Exner's crucial experiment, to show that two plates of silver, one in an atmosphere of chlorine and the other in an atmosphere of oxygen, but in metallic connection with one another, show a difference of potential. They point out that if this experiment had been properly performed it would have corroborated the result arrived at by Mr. Brown of Belfast, which in no way contradicts the contact theory, since every adherent of the contact theory, recognises a difference of potential between a metal and an oxide or chloride or any other salt of the metal, either in the wet or dry state. But Exner's experiment was carelessly performed, as instead of a metallic contact between a platinum wire used in the experiment and the silver plates there must have been a layer of chloride of silver between the metals.

In another of Exner's papers he states that the contact theory requires the E.M.F. of a Smee's cell to be at first 0·732 Daniell, and then to become less, and that the E.M.F. depends on the negative metal; whereas the chemical theory gives a much greater E.M.F. at the beginning if the liquid is oxygenated, and it can never become less than 0·732 D if zinc is prevented from being deposited on the negative metal. Many previous experimenters had proved that the latter statement is the true one, and its truth is shown by Exner's new experiments, which further show that whatever be the negative metal the E.M.F. must be the same. The authors point out that Exner's statement as to what the contact theory requires in a Smee cell is quite gratuitous, and indicates that he is not at all acquainted with the contact theory; they show that the sum of the contacts for a Smee cell published by them in the *Transactions* of the Royal Society, gives an E.M.F. greater than that of a Daniell. They quote also from Sir W. Thomson's well-known paper in the *Phil. Mag.* of 1851 a complete statement of what goes on in a Smee cell; of its primary E.M.F. being as much as 2½ Daniell's; of its *working* E.M.F. being what Exner says it is; as if Exner and all his predecessors' experiments on Smee's cell had been perfectly well-known to Thomson thirty years ago. Thomson, however, did not know that the nature of the negative metal is indifferent. This appears to be the only new fact given us by Professor Exner, but unfortunately for him it has been disproved by the more careful experiments of Beetz, who gives the following results for various

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

VOL. VIII.—No. 182.

THE BRITISH ASSOCIATION MEETING.

THE address of Professor A. C. Ramsay, the President of the British Association, although a masterpiece of its kind, was hardly one to excite general attention, the scope of the subject (geology) being necessarily narrow. The address of Professor W. G. Adams, the President of the Mathematical and Physical Section, was of a different nature, and is one likely to prove of considerable interest to scientific men generally. Departing from our usual course, therefore, we do not propose to give Professor Ramsay's address, but to give that of Professor Adams' at length, as follows:—

It has been said by a former President of this Section of the British Association, that the President of a Section ought to occupy your time, not by speaking of himself or his own feelings, but by a review, "more or less extensive of those branches of science which form the proper business of this section." He may give a rapid sketch of the progress of mathematical science during the year, or he may select some one special subject, or he may take a middle course, neither so extensive as the first nor so limited as the second.

There are many branches of science which have always been regarded as properly belonging to our Section, and the range is already wide; but it is becoming more and more true every day that the sciences which are dealt with in other sections of the Association are becoming branches of physics, *i.e.*, are yielding results of vast importance when the methods and established principles of physics are applied to them. I wish to direct your attention to investigations which are being made in that fertile region for discovery, the "border land" between chemistry and physics, where we have to deal with the constitution of bodies, and where we are tempted to speculate on the existence of matter and on the nature of the forces by which the different parts of it are bound together, or become so transformed that all resemblance to their former state is lost. It is not long since the theory of exchanges became thoroughly recognised in the domain of radiant heat, and yet it is already recognised and accepted in the theory of chemical combination. Just as the molecules of a body which remains at a constant temperature are continuously giving up their heat motion to surrounding molecules, and getting back from them as much motion of the same kind in return, so in a chemical compound which does not appear to be undergoing change, the combining molecules are continuously giving up their chemical or combining motions, to surrounding molecules and receiving again from them as much combining motion in return. We may say that each molecule is, as far as we can see, constantly dancing in perfect time with a partner, and yet is continuously changing partners. When such an idea of chemical motion is accepted, we can the more easily understand that chemical combination means the alteration of chemical motion which arises from the introduction of a new element into the space already occupied, and the consequent change in the motion of the new compound as revealed to us in the spectroscope. We can also the more readily understand that in changing from the old to the new form or rate of motion, there may be a development of energy in the shape of heat motion which may escape or become dissipated where . a means of escape presents itself. We know from the experiments of Joule and of M. Favre that as much heat is absorbed during the decomposition of an electrolyte as is given out again by the combination of the substances composing it.

We are making rapid strides towards the exact determination of those relations between the various modes of motion or forms of energy which were so ably shadowed forth, and their existence established long ago, by Sir William Grove in his Correlation of the Physical Forces, where, in stating the conclusion of his comparison of the mutual interchange of physical forces, he distinctly lays down the principles of energy in this statement, "Each force is definitely and equivalently convertible into any other; and where experiment does not give the full equivalent, it is because the initial force has been dissipated, not lost, by conversion into other unrecognised forces. The equivalent is the limit never practically reached."

The laws of Faraday, that (1) when a compound is electrolysed the mass of the substance decomposed is proportional to the quantity of electricity which has produced the change, and that (2) the same current decomposes equivalent quantities of different substances—*i.e.*, quantities of their elements in the ratio of their combining numbers, have given rise to several determinations of the relation between chemical affinity and electromotive force. In a paper lately communicated to the Physical Society, Dr. Wright has discussed these several determinations, and has given an account of a new determination by himself. The data at present extant show that when 1 gramme of hydrogen unites with 7·98 grammes of oxygen there are about 34,100 units of heat given out, making the latent heat of dissociation of *1 gramme of water equal to 3,797 units.* The results obtained are compared with the heat given out by the combustion of hydrogen and oxygen, and the value of the mechanical equivalent of heat is deduced from these determinations.

The value of this mechanical equivalent obtained by Dr. Wright, which depends on the value of Clark's standard cell, and, therefore, depends upon the value of the ohm, agrees fairly well with Joule's determination from the heat produced by an electric current in a wire, but is greater than Joule's value as obtained from his water-friction experiments. This may be accounted for by supposing an error in the value of the ohm or B.A. unit, making it too large by 1·5 or 2 per cent. Kohlrausch has also made comparisons of copies of the B.A. unit with standard coils, and comes to the conclusion that the B.A. unit is 1·96 per cent. too large. On the other hand, Professor Rowland, in America, has made a new determination, and finds that according to his calculations the B.A. unit is nearly 1 per cent. too small. These differences in the values obtained by different methods clearly point to the necessity for one or more new determinations of the unit, and I would venture to suggest that a determination should be made under the authority of this Association, by a committee appointed to carry out the work. And it is not sufficient that this determination should be made once for all, for there is reason to think that the resistance of standard coils alters with time, even when the material has been carefully selected. It has been found that coils of platinum silver which were correct copies of the standard ohm

WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My letter to you of the 30th September was written with the object of getting Mr. Gordon to enter into a correspondence about the assertion in his book, "The cushions are connected with the ground so that the negative electricity produced on them can escape." His reply in your issue of the 16th October was virtually a refusal to enter into correspondence, but I am glad to find through his letter in your issue of 30th October that he has changed his mind, and has admitted that the passage in question is wrongly worded, and that he will amend it in the next edition of his book. This is just as it should be. An experimenter in, and writer on, science is looked upon as a false guide if he does not make the attainment of scientific truth the mainspring of his actions. Now that Mr. Gordon is following in the right course, it is interesting to trace his views as to what he does regard as being the truth. The change he proposes to make in the second edition of his book on the above quoted passage is to remove the word "escape," and substitute for it the word "disappear." This proposal proves that Mr. Gordon is mentally in a state of great darkness as to wherein the passage is wrong. The error lies in his assumption, according to Dufay's two-fluid theory and Faraday's two-force theory, that there is formed on the cushions negative electricity, which is either to "escape" or "disappear" by a connection being made with the ground. This is wrong. The cushions take electricity from the ground, then deliver it to the glass, and the glass transfers it to the prime conductor. It is one electric fluid which passes through the machine. It is amazing that Mr. Gordon does not see that the passage in question commits him to Dufay's two-fluid or Faraday's two-force theories. The passage in question is far from being the only one in his book which commits him to being an upholder of one or other of these duplex theories, which are both wrong.

Again, Mr. Gordon writes in his last letter to you, "Let us attach a wire from the rubbers to the knob of a positively charged Leyden jar. Then, when we work the machine, the positive charge will be diminished. We may either say that some of the positive electricity has been drawn up the wire, or that negative has flowed down it, and neutralised some of the positive. We have no means whatever of distinguishing which is the correct view." If Mr. Gordon had read with attention your reprint of my letter of 1839, he would have seen that there was pointed out therein the means of determining the direction of a current of electricity. I shall now describe it more minutely. Let Mr. Gordon insulate a friction electrical machine entirely by placing vulcanised india rubber or blocks of paraffin wax below the base of it, and clothe the handle of it entirely with vulcanised india rubber. This will conserve all the electricity collecting power of the machine. Let him now take a copper wire from the rubbers to the ground, or still better to the water-pipe of his house. Let him now cut this wire in two near the machine, and place a small brass ball on each end of the wire where cut. Let him now adjust the two balls so that the distance between them is such as lets the electricity pass easily from the one to the other when the machine is in motion. Let him now place between these two brass balls a flame of gas well insulated by passing through a glass tube, and let the flame be free from smoke. If the size of the flame is properly adjusted so that the current of electricity has full power over the flame, he will find that whenever he sets the machine in motion and keeps it moving steadily the flame will bend down in one direction, and will never fluctuate backwards and forwards as a pith ball would do, but, on the contrary, it will always bend down in one direction, and this direction indicates the direction in which the current of electricity is moving. A pith ball is deceitful because it takes on a coating or charge of electricity, and therefore dances backwards and forwards. The insulated gas flame cannot receive a coating or charge of electricity, and therefore it does not fluctuate in its movements. Mr. Gordon will find it utterly impossible to get the insulated gas flame to indicate that a current of electricity ever goes from the rubbers to the ground. The flame always indicates that the current of electricity goes from the ground to the rubbers.

This establishment of the fact that no negative electricity accumulates on the rubbers requiring to be allowed to "escape" or disappear, demolishes Dufay's theory of two fluids and Faraday's theory of two forces.

There are some other very important matters in Mr. Gordon's last letter, but at present I refrain from making comments on them, because it is best in controversy to exhaust one subject before going to another. Will Mr. Gordon try the experiment of the gas flame and let you know if he can get it to indicate that a current of electricity goes from the rubbers to the ground?—

Yours, &c.,

JAMES JOHNSTONE.

DES FORCES ÉLECTRO-MOTRICES

DE CONTACT DANS LES ACTIONS VOLTAÏQUES

On doit se rappeler la discussion fameuse qui s'éleva au commencement de ce siècle entre Galvani et Volta et qui eut pour dénouement la découverte de *la pile voltaïque*. On sait que Volta, ne voulant pas admettre que l'électricité dégagée dans l'expérience de Galvani fût d'origine animale (*le fluide galvanique*), montra que les mouvements de contraction de la grenouille devaient surtout être rapportés à ce que l'arc métallique qui réunissait les nerfs lombaires aux muscles de l'animal, dans cette expérience, était *composé de deux métaux différents*. De *ce contact* devait résulter, suivant lui, la création d'une force à laquelle il donna le nom *de force électro-motrice* qui devait provoquer un dégagement électrique capable de produire les effets de contraction observés, du moins, quand on venait à provoquer la décharge à travers l'animal, en réunissant métalliquement deux parties de son corps susceptibles d'excitation électrique. Cette opinion fut combattue par les partisans de Galvani, et c'est alors que, pour convaincre ses adversaires, Volta entreprit ses célèbres expériences qui le conduisirent à la création de sa pile. Après cette découverte, l'opinion de Volta fut généralement admise, et elle prédomina pendant plus de trente ans; mais la découverte de *l'électro-chimie* et les expériences remarquables de MM. Becquerel et de la Rive ouvrirent un autre champ aux hypothèses, et on prétendit bientôt que ce n'était pas le contact physique de corps hétérogènes qui provoquait dans la pile de Volta, le dégagement électrique, mais simplement les actions chimiques qui y étaient en jeu, et surtout *l'oxydation du zinc*. Dès lors, on voulut supprimer le mot *force électro-motrice* qui rappelait trop la théorie de Volta, et pendant quelque temps on regarda comme *retardataires* ceux qui employaient encore cette expression, même en admettant la théorie électro-chimique. Toutefois, certains physiciens, surtout en Allemagne, ne furent pas convaincus, car il y avait bien des cas où la théorie électro-chimique était en défaut. Ainsi, par exemple, comment pouvait-on expliquer, dans cet ordre d'idées, cette expérience qui montre que du zinc chimiquement pur n'est attaqué dans l'eau acidulée que quand il est électrisé positivement?... Si l'action *chimique* était, dans cette expérience, *la cause déterminante*, l'oxydation du zinc devrait *précéder le dégagement électrique et non en être la conséquence*. Cette expérience et beaucoup d'autres encore, montrèrent qu'il fallait rechercher ailleurs, sinon la cause principale, du moins *l'action déterminante*, et l'on se trouva conduit à admettre, comme Volta, que cette cause déterminante ne pouvait être autre que celle résultant du contact physique des corps hétérogènes, mis en présence dans la pile, contact que l'action chimique pouvait renouveler sans cesse et dont l'effet pouvait être rendu *continu* par cela même. On put aussi, par cette hypothèse, rendre à l'action chimique le principal rôle, en faisant remarquer qu'elle se trouvait surexcitée alors par l'action électrolytique résultant du passage du courant.

Une fois lancé dans cette voie, on dut reprendre naturellement la désignation de *force électro-motrice* donnée par Volta et adoptée par Ohm, et des expériences pour mesurer cette *force électro-motrice de contact* furent entreprises dans les différents pays avec un succès plus ou moins grand. Toutefois, beaucoup de physiciens ne sont pas encore convaincus,

Confidential," but the injurious effect such "news" on cable property leads us to say that for more twelve months we have had before us a prospectus marked "The American Cable Company of New York." This prospectus states that "the system of cables will start in America from New York, and extend to the island of Flores, &c." It also states that the Company will have the "Exclusive use of new apparatus, which will double the working speed, &c."

It is impossible to read these extracts and compare them with the *Standard* telegram without suspecting the concoctors of sinister designs upon the share market.

CORRESPONDENCE.

WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Now that Mr. Johnstone has sent to you a scientific argument I am delighted that we should discuss the question with, I hope, that mutual benefit which seldom fails to follow the exchange of ideas on scientific subjects.

I will first point out that all through my book I have been most careful not to say anything committing myself to the theory of one fluid or of two. I think either would explain most electrical phenomena equally well, and that there is absolutely no proof of the truth of the one or the other, or of either. They are both merely convenient conventional ideas to assist us in describing phenomena which we cannot explain.

I know, however, the danger of using these sort of conventions, as the mind is very apt, after a time, to cease to distinguish between what is known experimentally, and what is assumed provisionally as a convenient method of simplifying our language when describing any unexplained phenomenon.

I, therefore, deeply regret it, as appears from "J. L.'s" letter, I have led any student into error by what I must confess was a somewhat careless expression. I can only plead in extenuation that I believe it is the only passage in my book which commits me to either theory.

I propose, therefore, in the next edition, to alter the sentence as follows. Instead of "that the negative electricity produced on them may escape," I will write, "that the negative electrification produced in them may disappear." I think that with this correction the passage will be as accurate as our present knowledge of the science permits.

If we assume the ideas of one or two fluids to be theories, and not mere conventions, we may "prove" either by experiment as follows:—Let us attach a wire from the rubbers to the knob of a positively charged Leyden jar. Then, when we work the machine, the positive charge will be diminished. We may either say that some of the positive electricity has been drawn up the wire, or that negative has flowed down it and neutralised some of the positive. We have no means whatever of distinguishing which is the correct view.

Let us suppose a balance placed in an inaccessible room, where we cannot see it, but having a pointer fixed to an axle passing through the wall. Then, if that pointer moves, we know that a difference has been made in the weights in the two pans, but we have no means of knowing whether the difference has been caused by the taking out of weights from one pan or by the adding of weights in the other. And, further, if instead of a pointer attached to the axis, there was a cog-wheel working into a rack carrying an index, then, as that index moved up or down, we should know that the beam of the balance was moving, but if we did not know on which side of the cog wheel the rack was placed, we should not know which direction of motion of the index corresponded to a given motion of the balance; although, if we had to speak much about it, we should probably call one motion of the index the positive motion, and the other the negative.

Similarly, in electrical phenomena, no doubt all manner of beautiful and complex actions take place in conductors carrying currents, but, alas, they are like the balance in the closed room, and we can only (as yet) see the few simple motions of the index.

I have said "I do not know the direction of the flow, or even if it has a direction at all."

When two conductors of different potentials are connected by a wire, the potentials commence to equalise themselves, and as long as this equalisation is going on the wire exhibits certain properties. It is heated, but if of even resistance it is heated equally all along, we cannot say the heating begins at one end or the other. It exhibits certain electrical and magnetic properties, but we cannot say that they are produced at one end sooner than they are produced at the other,* and here I think our actual knowledge ends. When two differently electrified bodies are brought to the same state of electrification by connecting them by a wire, we say that there has been a flow of electricity along the wire, because, *assuming that electrification is produced by an excess or defect of a fluid or fluids*, then an equalisation of potentials similar to what does actually take place would be produced if a portion of this fluid had passed along the wire.

When I was a student in Professor Clerk Maxwell's laboratory I remember his trying an experiment to see if an electric current was a flow of anything having inertia. He revolved a coil of wire, carrying a current, rapidly round the axis of the coil, and then stopped the motion suddenly, and looked for an extra current, but got no effect.

Lately Professor Holtzmann has indicated a possible method of determining the direction of flow, but, as far as I remember, he got no conclusive result. I have not his paper by me at this moment, but will send you a note of it later on.

We now come to Mr. Johnstone's experiments, but I fear that, however ingenious they are, they are hardly conclusive.

Firstly, I understand Mr. Johnstone to consider that because a shock can be obtained from a Leyden jar, whose coatings are charged to two different positive potentials, there cannot be negative electricity.

This is nearly equivalent to saying that because the number 10 is the difference between 5 and 15, that it cannot be the difference between + 5 and − 5. All shocks, and other similar phenomena, depend on the sudden connecting by a conductor of bodies electrified to different potentials. A given difference of potential will produce the same effect whether the potentials themselves are high or low. For instance, the effect produced by connecting two electrified bodies whose potentials differ by 2 would be exactly the same whether the potentials were 100 and 102, + 1 and − 1, or − 100 and − 102. As an experimental illustration of this, let a battery be connected to a galvanometer, and both placed on an insulating stand and the deflection noted. The deflection depends on the difference of potential between the poles of the battery. Let now the whole system be electrified either positively or negatively to any extent, say by connecting a wire from a machine to the fluid of the battery. The deflection will remain unchanged, showing that it depends on the difference of the potentials, and not on the potentials themselves.

The earth is arbitrarily chosen as the zero of potential, and bodies of lower potential than it are said to be negatively electrified.

Secondly, the experiments with the gas flame give us some interesting information as the action of charged conductors on particles of heated air or gas. Under certain circumstances, depending on the potential of the flame, there is attraction, and under others a repulsion, but I fail to see how this affects the question of the direction of the flow of electricity. How do we know that the motion of the gas particles is the same as that of the electricity? We might as well attempt to deduce the direction and speed of flow of a river from the motion of waves on its surface.

If Mr. Johnstone's view is correct we could determine the velocity of an electric current by putting an anemometer in the stream of heated air coming from the attracted or repelled gas flame.

Thirdly, "the tinfoil is unnecessary." Certainly. The only essential parts of a Leyden jar are two electrified surfaces and an insulator to separate them. It does not in the least matter whether the charges are spread over the surfaces of the glass by charging every part of it, or by sheets of tinfoil, or, as was probably the case in the experiment quoted, by films of moisture.

Fourthly, electricity will pass through glass. It passes through all substances in inverse proportion to their resistances. The resistance of glass at 200°C. is, roughly speaking, about 300,000 times that of water at 22°C. I do not quite see, however, what conclusion as to the existence or non-existence of one or two fluids can be drawn from this fact.

In my "Electricity," in my "Four Lectures on Induction," and in a lecture delivered at the London Institution (*Electrician*, Jan. 31, 1880), I have put together accounts of such facts as are actually known about the state of insulators across which electric actions are taking place. With regard to the state of conductors we have no knowledge whatever. A few years ago

* I am aware of Wheatstone's experiment with the revolving mirror and the three sparks, but I think electricians are agreed that the retardation is simply due to the gradual charging of the condenser, consisting of the wire and its insulator, as it does not give any real information about the direction of flow.

SCIENCE.

SATURDAY, MARCH 4, 1882.

ELECTRIC CONDUCTION AND DISCHARGE.

By F. E. Upton.

The question of the nature and the vehicle of the electrical discharge is an important one, and its determination will contribute greatly to the solution of many interesting problems in cosmical physics. It is desired in this article to call attention to some recent advances that have been made in this direction.

The view that the phenomenon is one of pure conduction, though it has received the attention of eminent physicists, can be said to be no longer entertained.

When a conductor is made to connect two poles or electrodes which are at a different potential, it is well known that the greater the cross section of the conductor, or in other words, the more of the conducting material is laid bare by a cross section, the *less* resistance will be offered to the union of the electricities of the two terminals, and the greater will be the ensuing current, with a given E. M. F.

Now, in the discharge, the contrary is observed directly. This characteristic of conduction is absent when the discharge takes place; in a tube containing air, the greater the pressure (above a certain inferior limit), or the more of the conducting material there is laid bare by a cross section, the *greater* will be the resistance to the passage of the spark, and the nearer together the terminals will have to be brought to effect a spark with a given difference of potential. Sir Wm. Snow Harris, in 1834, made an attempt to grasp at the law governing the relation of the length of spark to pressure; and he then stated that the length of spark is in the simple inverse ratio of the pressure. Gardon, in 1878, made a series of experiments to test this law, (Elec. and Mag. ii. 55-62). He found that from a pressure of about eleven inches to that of the atmosphere, Harris's law held approximately good.

Representing resistance by r, and matter laid bare by cross section by s, in the case of conductor $r = \frac{1}{s}$; in the case of discharge $r = s$, approximately. Thus there is in question two entirely different order of phenomena.

Another distinctive characteristic of conduction will be recognized in the fact that whenever there is any conductor at all, however small and however long it may be, connecting two poles, some degree of current will flow, as long as there is any difference of potential. With discharge, however, a certain lower limit of distance apart, of poles, and of interposed matter, is requisite for any current at all, and when that limit is reached the spark passes, instantaneously, and the discharge commences.

Whether the current passes by conduction or discharge, heat is equally developed; in the conductor in the one case, and in the interposed matter in the other. This common development of heat does not in any way assimilate the two phenomena. The condition of affairs in the two cases will perhaps become obvious if recourse is had to the corresponding hydraulic analogy.

Imagine a pond of water held in place by a dam, with a pipe leading from the bottom of the dam, for the purpose of drawing water from the pond. The smaller that pipe is in section, the smaller will be the current of water flowing through it under a given head, and a certain amount of heat will be developed by friction of the water against the interior of the pipe; moreover some degree of current will flow as long as the pipe has any size of cross section at all. That corresponds to conduction. Now let the pipe be imagined closed to the exit of water; as long as the dam is sufficient, no current at all will flow; but suppose the dam be diminished in thickness gradually and constantly, a point will be eventually reached when it will no longer suffice to hold back the water, which will break through the impediment; the friction of the water against the fragments of the dam, and of those fragments against each other will develop heat as in the first case. That corresponds to the discharge.

By this analogy the difference between conduction and discharge is clearly apparent. A conductor between two points at a different potential never offers any *resistance* to the passage of the current, strictly speaking. Instead of saying that a slender wire offers more resistance than a thick one, it would give a better understanding of the matter to say of the latter that it offered a freer passage to the current than the former. In the case of discharge, on the contrary, the matter interposed between the points acts always as a bar, or resistance to be overcome, and the more there is of it the more resistance. It is never an aid or way.

Mr. E. Goldstein, in the *Annalen der Physik*, describes an ingenious experiment bearing upon this point, which, if not conclusive, is entitled to some consideration. In a discharge tube which was filled with dry nitrogen, he placed a little sodium, which could be vaporized by heating. The positive light had a purplish red color, but in the vicinity of the sodium it was of a golden yellow. By careful heating and manipulation, the upper half of the tube could be kept red and the lower half yellow. Now the tube was brought over and near, in a horizontal and equatorial position, to a powerful magnet. The discharge light was repelled as a slender thread to the opposite (upper) side of the tube; but it was a pure reddish thread, and showed no trace of sodium yellow. So the sodium was not displaced or repelled under the influence of the magnet, as it would have been had it been a *conductor* of electricity.

There has been considered the possibility that metallic particles thrown off from the electrodes might be the conductors of the current. To determine if this were the case, Mr. Goldstein made use of a tube with platinum electrodes, in which the light from the kathode was deflected by a second kathode. The light alone underwent this deflection, while the minute particles torn off from the platinum, which lodged on the opposite wall of the tube and formed a sort of mirror there, went exactly to the same point after the deflection of the light, as before. There was thus no connection between the light of discharge and the abraded metallic particles.

But the most elegant demonstration in this matter has been furnished by the experiments of De La Rue and Müller: they arranged that the discharge of 2,400 chloride of silver cells should pass through a circuit consisting of a vacuum tube and a large variable resistance, R; now with different resistances R_1, R_2, the resistance of the vacuum tube formed a varying fraction of the whole resistance; and, according to Ohm's law for the fall of potential along a conductor, the fall of potential along the vacuum tube should have been variable, had its function been that of a conductor. It was found in fact, however, that the fall of potential along the tube remained constant, no matter what resistance was introduced in the remaining part of the circuit between the poles of the battery, showing that the discharge was not a case of true conduction, but that even at the lowest pressure it was disruptive.

38

ELECTRIC CURRENTS.—Professor Sylvanus Thompson, of Bristol, delivered a lecture on February 22, at the Crystal Palace, on "Electric Currents: What are they?" This lecture is the first of a series which the directors of the Palace have organised in connection with the International Exhibition of Electricity. The lecturer began with an enumeration of the multifarious services now rendered to mankind by the electric current. Yet, though its applications were endless, it was remarkable how little was known of its intimate nature. To understand the true nature of electric currents, or even of electricity itself, necessitated a wide range of study, the more careful because of the great variety in the different properties and phenomena. Electricity might remain in the form of "charges" on the surface of bodies, or might flow through their substance in continuous "currents." Yet it was not a material fluid, and the term "electric fluid" was now only used by those who knew nothing about modern investigations in the science. Nevertheless a study of the various properties of electricity, the attractions and repulsions it set up, the sparks to which it gave rise, the chemical decompositions it effected, the magnetic actions it produced, all led toward a certain theory, only to be grasped when all these diverging lines were traced back to their logical origin. It was a matter of congratulation that so many eager and able scientific men were now devoting themselves to this youngest of the sciences, more especially as it was pre-eminently a British science. Almost every great discovery in electricity had been made by Englishmen. From the time of Dr. Gilbert, who founded the science in 1600, Englishmen had been foremost in electric discovery. Stephen Grey discovered that electricity could be made to flow in currents through wires; John Canton discovered the influence exerted by electricity at a distance; Benjamin Franklin, the inventor of the lightning rod, was a Briton, though resident then in Philadelphia; Humphry Davy, the discoverer of the electric light; Spencer, the inventor of electro-plating; Faraday, the greatest experimentalist in electric science that ever lived, to whose fundamental discoveries modern dynamo-electric machinery may be directly traced; Ronalds, Cooke, and Wheatstone, the fathers of the electric telegraph, and Swan, the inventor of the carbon-filament lamp, were all Englishmen, while Graham Bell, the perfector of the telephone, was Briton-born. Not that some great discoveries had not come from other lands. Cuneus, a Dutchman, discovered the Leyden jar; Volta, an Italian, discovered the voltaic cell; Oersted, a Dane, discovered the relation between magnets and electric currents; Reis, a German, invented the first rude telephone by which articulate speech was transmitted; and Planté, a Frenchman, invented the storage-battery or accumulator. After referring to the relation between the power of electric currents and the power that is spent in producing them, Professor Thomson spoke of the certainty that in the near future all heavy mechanical work would be done by electric currents in the place of steam, a theme which will claim further attention in a subsequent lecture. Developing the question of the production of electric currents in voltaic batteries, the lecturer referred to the discovery that such batteries were reversible, and that in this reversibility lay the newly-discovered power of storing or accumulating electric energy in cells which could be charged and discharged at pleasure. The magnetic, thermal, and physiological properties of the electric current were illustrated experimentally, the lecturer remarking with much emphasis that the mistake of confounding physiological with medical or remedial effects led to the gross impositions of the quacks and rogues who deal in so-called magnetic appliances, and disgrace alike the sciences of electricity and of medicine, while knowing nothing of either. The nature of electric currents was reverted to, and an outline was given of the theory of Clerk Maxwell that all electric phenomena were due to actions going on in the thin medium that fills the whole universe—the ether—vibrations of which are light and heat, the accumulations of which are electric charges, the streams in which are electric currents, and which, where it was made to spin round in vortices or whirlpools, gave rise to magnetic attractions. In conclusion, the lecturer commented on the immense importance of the revolution now beginning in the substitution of electric machinery for steam engines, and urged that if England desired to reap the benefit of this impending reorganisation of the methods of mechanical production, if she desired that her workmen should rise to the immense future before them, she must not lose an hour in providing them with an education in matters electrical, seeing that a knowledge of electric currents and their properties will be of far more practical importance than a knowledge of any other branch of science. If technical education did not come in any other way, it would be forced upon us by the practical fact that electricity is to be our servant in the place of steam and of coal.

39

PROF. ROWLAND'S NEW THEORY OF MAGNETIC ACTION

PROF. ROWLAND has lately published in the *American Journal of Mathematics* (vol. ii., No. 4; vol. iii., Nos. 1 and 2) a series of papers on "The General Equations of Electromagnetic Action with application to a New Theory of Magnetic Attractions, and to the Theory of the Magnetic Rotation of the Plane of Polarisation of Light." The papers, in addition to what is stated in their title, contain the mathematical consideration of that action of magnetism on electric currents which was lately discovered by Mr. Hall, and it is proved in them that, if Maxwell's theory of light be true, this action will explain the magnetic rotation of the plane of polarisation of light. These papers will no doubt be very extensively read, both on account of the interest of their contents and the great reputation of their author, and a brief discussion of them may therefore not prove uninteresting to the readers of NATURE.

We shall commence with the "New Theory of Magnetic Attractions." This theory is of the simplest kind, and obviously suggested by the mathematics of the subject. Since the magnetic induction is related to the distribution of the vector potential of magnetic induction in exactly the same way as the angular rotation of an element of fluid is to the distribution of velocity in the fluid, Prof. Rowland suggests that the magnetic field consists of a perfect fluid, whose velocity at any point is represented in magnitude and direction by the magnetic vector potential at the point, the vortex lines in this fluid are the lines of magnetic induction, and the velocity of angular rotation, is proportional to the magnitude of the magnetic force. Again, since 4π times the electric current is related to magnetic induction in the same way as magnetic induction to the vector potential, Prof. Rowland considers that an electric current consists of, as it were, vortices of vortices, or in other words, that certain irregular distributions of the vortices constitutes currents.

Maxwell has proved that the forces existing in the magnetic field could be produced by a certain distribution of stress in a medium filling the field. This stress in the simplest case consists of a tension along the lines of force equal to $\frac{H^2}{8\pi}$, along with a pressure at right angles to the lines of force equal also to $\frac{H^2}{8\pi}$, H being the intensity of the magnetic force.

Prof. Rowland goes on to show that this state of stress exists in the medium, which, according to his theory, fills the magnetic field; his proof is as follows:—"Conceive the fluid in a tube to be rotating around the axis with a certain velocity, and suppose the ends of the tube to be closed with movable pistons. Then, if the pistons are left free, there will be a centrifugal force against the sides of the tube proportional to the square of the velocity of angular rotation. If the walls are flexible and the piston immovable, then there will be a force tending to press the pistons in, and proportional also to the square of the velocity. According to our theory the magnetic force is the velocity of rotation, and so we have in the medium a tension along the lines of force and a pressure at right angles to them." Prof. Rowland does not seem to have noticed that this explanation requires the vortices to be of a finite size. It is easy to prove that in a cylindrical vortex of radius a, density ρ and angular rotation ω, the intensity of pressure on the circumference of the cylinder is greater than the mean intensity of pressure on the ends by $\frac{\rho\omega^2 a^2}{4}$; but if this is to explain the magnetic attractions the difference must be $\frac{H^2}{4\pi}$. Hence if $H = c\omega$, where c is a constant, we must have $\pi\rho a^2 = c^2$, $a = \frac{c}{\sqrt{\pi\rho}}$; we thus get a definite value for a, and the vortices must not be capable of division into bundles of smaller radius than a. Thus the fluid by which Prof. Rowland explains magnetic action cannot be the indefinitely divisible fluid treated of in theoretical hydrodynamics. It is worthy of remark that in the theory of magnetism put forth by Maxwell in the *Phil. Mag.* for 1861-62, and which agrees with the theory we are considering in explaining magnetic force by the angular rotation of a fluid, the vortices have a finite size, being done up as it were into cells, the space between the cells being filled with particles whose motion, according to Maxwell, constitutes electric currents.

Let us now go on to the explanation Prof. Rowland gives of the production of the magnetic field. He says: "Let the nature of electromotive force be such that it tends to form vortex-rings immediately round itself, not by action at a distance, but by direct action on the fluid in the immediate vicinity. The first ring will then move forward, another one will form, and so on until the whole space is filled with them, when there will be equilibrium." The consequences of this explanation, vague as it is, are somewhat startling. In the first place it is clear, from the properties of vortex motion, that every chain of particles of the fluid which possess rotation at any time must at some previous time have been in the immediate vicinity of the electromotive force; and since according to the theory there is rotation of the fluid at every point in the magnetic field, it follows that in the time taken to set up the field every particle of fluid in it has been in the immediate neighbourhood of the electromotive force. But magnetic disturbance is propagated, according to Maxwell's "Theory of Light" (which Prof. Rowland accepts), with the velocity of light; hence the streams of the fluid must be flowing with the velocity of light, and in addition every particle of fluid in the field must have rushed through the small space occupied by the seat of the electromotive force in the short time it takes to establish the magnetic field. Another difficulty which Prof. Rowland does not explain is the following: If we take a small element of electromotive force we know that to agree with the distribution of magnetic force all the vortex-rings must have the same sense of rotation; but if vortex-rings have the same sense of rotation they move through the fluid in the same direction, so that these vortex-rings when produced would all move off in the same direction, and thus leave one half of the field without rings, *i.e.*, without magnetic force. Again, the way in which these rings spread out so as to fill the field would seem to be in contradiction to the laws of vortex-motion; but as the author says he is investigating the dynamics of the subject, we may leave further comment on this point till the result of his investigation appears.

The explanation of the stress in the medium which we have referred to before is the only application of the theory worked out by Prof. Rowland. He does not explain by it any of the phenomena of induction, nor does he get from it any connection between statical and current electricity; yet he does not hesitate to speak of his theory "as one link in the chain, the first three links of which have been added by Thomson, Helmholtz, and Maxwell."

We must now leave this part of the subject and pass on to that portion of the paper which treats of the general equations of the electro-magnetic field. The mathematics of this is merely an application of the theory of the vector-potential to currents. The most important feature in the treatment of the subject is that Prof. Rowland always writes the product of the conductivity into the electromotive force instead of the intensity of the current, and claims that this is an important advance; but if there is any difference either Ohm's law must not be true, or Prof. Rowland must mean by electromotive force something different from that meant by ordinary users of the term. Prof. Rowland asserts that in an unlimited medium the action is not between magnets and currents, but between magnets and electromotive forces; he bases this assertion on the theorem that in an unlimited medium unclosed electric currents have no magnetic action. It is hard to see how this proposition can be true, for the current through any area is measured by the line integral of the magnetic force round the boundary of the area; but if the magnetic force is everywhere zero, then the line integral of it round any curve must vanish, and thus the current at any point must vanish. The proposition is based on reasoning of the following kind: the force between an electric point (by an electric point he means a point from which electricity is streaming, in fact what is usually called a source) and a magnetic pole must by symmetry lie along the line joining them. But a magnetic pole of any size is always accompanied by one of the opposite sign, and the two form a vector quantity; and we think from the relation that one pole necessarily bears to another, it is not safe to reason about it as if it were a purely scalar quantity. Prof. Rowland himself acknowledges what is equivalent to this, for after saying that the force due to the unclosed currents on each pole of the magnet is zero, yet he says there is probably a force on the magnet as a whole tending to place it across the currents.

Although we think that the reasoning given for the assertion that the action is not between magnets and currents, but between magnets and electromotive forces, is unsatisfactory; yet we think that, understood in a certain sense, the proposition is mathematically true. For we can prove directly from the ordinary expressions for the magnetic action of currents, that if we have a source and a sink of equal intensities ($4\pi m$) placed close together, the magnetic action of the currents produced is

40

what strength the spring has got. Select a mainspring as near like the old one as you can. Some jobbers tell the strength by laying the spring on the first and second finger, and pressing their thumb on the middle, having the old one in one hand and the new one *in* the other. Then they reverse them. A gauge is easily made by two pieces of brass being riveted and soldered together (Fig. 31). First get width with your callipers, then thickness with Fig. 31. Having selected your spring, get length by old one; soften the outside end about an inch, file it, and make it weaker. Now taper the end and punch for rivet (see Fig. 31); now file up a piece of soft steel wire, size of hole in barrel; cut off inside after allowing for rivet; then place it in your pinvice and file up as shown (Fig. 32). Chamfer the inside of the hole in the spring; now place rivet in the vice. Put the spring on it; see that you have got it the right way; now with a small hammer keep tapping round the outside of the rivet. Don't touch the middle. As soon as it gets oval, file it flat. In this way you will make a good strong rivet. Leave it a *little* oval at the finish as a support to the outside; now cut off about the length required for the barrel—you can measure from the outside; file it level and polish the end. You can buy a mainspring winder for about 1s. 6d., but you can make a simple one (Fig. 33). Place the spring between your fingers, as shown in Fig. 34; put the winder between your fingers; when you have got it wound up, place your thumb upon it as shown (Fig. 35); pick up your barrel and put in spring. If you can't do it this way, you can do it by putting the outside end in its place in the barrel, and work it in, coil after coil...

ENGLISH MECHANIC AND WORLD OF SCIENCE:

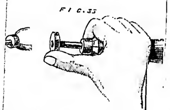
April 7, 1882.

THE APPLICATIONS OF ELECTRICITY.*

I WILL endeavour, in two lectures, to review the principal applications of electricity, which you have seen working in the recent remarkable exhibition of the Palais d'Industrie. From a practical point of view we may divide electricity in two chapters: statical electricity, which is produced by friction; and dynamical electricity, which is obtained by chemical or by magnetical action. Statical electricity has so very few applications

FIG. 32.

FIG. 33



that I may almost pass it over in silence. I will only remind you that the old-fashioned frictional machines are now superseded by dielectric machines, such as Holtz's and Carré's. At the exhibition you may have noticed machines with several dozen plates turning simultaneously, and giving very powerful effects.

We will at once turn our attention to voltaic or dynamical electricity, which has received an endless number of applications, among the most important of which are telegraphy, telephony, and galvanoplasty, which will form the subject of my first lecture.

The source of electricity generally used in these branches of the science is chemical action. You remember that Volta's pile was composed of rounds of copper, wet cloth, and zinc, always piled up in

* Lectures delivered by C. Detaille, at the Palais du Trocadéro, Paris.

THE TIMES, THURSDAY, NOVEMBER 16, 1882.

SIEMENS ON ELECTRIC LIGHTING.

...meeting of the winter session of the ... was held last night in the rooms of the ... street, Adelphi, and there was a large ... scientific men to hear the address of Dr. ... newly-elected Chairman of the Council.

...MENS, who was warmly received on entering the ..., took the chair, his address being read by his secretary, Mr. Runher. The address was devoted almost entirely to a consideration of the present condition and future prospects of electric lighting. The two principal difficulties, Dr. Siemens said, which had always stood in the way of the practical introduction of the electric light were the cost of producing the electric current by means of a battery and the mechanical difficulty of constructing suitable lamps. The first of these difficulties had been disposed of by the dynamo-machine—a machine now so perfect that little advance could be expected in its construction. A well-constructed dynamo converts more than 90 per cent. of the mechanical force imparted to it into electricity, and 90 per cent. of this again can be utilized for the production of light. The margin of loss, therefore, does not exceed 20 per cent., excluding purely mechanical losses, and this is quite capable of being reduced to some extent by improved modes of construction; but it results from these figures that no great step in advance can be looked for in this direction. The dynamo-machine presents the great advantage of simplicity over steam or other power-transmitting engines; it has but one working part—namely, a shaft, which, revolving in a pair of bearings, carries a coil or coils of wire admitting of perfect balancing. Frictional resistance is thus reduced to an absolute minimum, and no allowance has to be made for loss by condensation or badly-fitting pistons, stuffing-boxes, or valves, or for the jerking action due to oscillating weights. The materials composing the machine—namely, soft iron and copper wire,—undergo no deterioration or change by continuous working, and the depreciation of value is therefore a minimum, except where currents of exceptionally high potential are used, which appear to render the copper wire brittle. The essential points to be attended to in the conception of the dynamo-machine are the preventing of induced currents in the iron and the placing of the wire in such a position as to make the whole of it effective for the production of outward current. These principles, which have been clearly established by the labours of comparatively few workers in applied science, admit of being carried out in an almost infinite variety of constructive forms, for each of which may be claimed some real or imaginary merits regarding questions of convenience or cost of production. This fact, together with the public interest which had been aroused by the various displays of electric lighting, commencing with the illumination of the Place de l'Opéra in the year of the Paris Exhibition and ending with the recent exhibitions in Paris and at the Crystal Palace, had greatly encouraged the growth of companies for the purpose of introducing electric light. New companies for the purpose of introducing electric light and power had been announced almost daily, though their real claim to public attention as investments was based in some cases upon only very slight modifications of well-known forms of dynamo-machines, of arc regulators or of incandescent carbon lights, the merits of which rested rather upon anticipations than upon any scientific or practical proof. These arrangements were supposed to be of such superlative merit that gas and other illuminants must soon be matters simply of history, and hence arose the depreciation in gas shares caused by the premature announcement in 1878 of the accomplishment of the subdivision of the electric light by incandescent wire. It should be borne in mind, however, that any great technical advance is necessarily the work of time and of serious labour, and that when accomplished, it is generally found that, so far from injuring existing industries, it calls additional ones into existence to supply new demands, and thus gives rise to an increase in the sum total of our resources. It was therefore reasonable to expect that, side by side with the introduction of the new illuminant, gas lighting will go on improving and extending, although the advantage of electric light for many applications, such as the lighting of public halls and warehouses, of our drawing-rooms and dining-rooms, our passenger steamers, our docks and harbours, are so evident, that its advent might be looked upon as a matter of certainty. Commenting upon recent legislation on this subject, Dr. Siemens spoke favourably of the Electric Lighting Act passed last year, and seemed to think that the complaints now appearing in the papers that municipalities refuse their assent to applications by electric light companies for provisional orders were often not well founded. The authorities would clearly be justified in refusing any applications of a speculative character, and no licences or provisional orders should be granted unless the applicants could give assurance of being able and willing to carry out the proposed work within a reasonable time. The technical questions involved are hardly yet sufficiently understood to admit of immediate operations upon a large scale. The area that each lighting district should comprise varied according to the opinion of different witnesses before the recent Parliamentary Committee, from Dr. Siemens's own estimate of a quarter of a square mile to estimates suggested by others of as much as four square miles. In the case of gas, considering the unpleasant nature of the manufacture, it was necessary that the supply should range over a large area; in the case of electricity this did not apply, and for many reasons it might be desirable to limit the size of each district to that above-mentioned—a quarter of a square mile. Such is about the area of the parish of St. James's; and Dr. Siemens then proceeded to sketch out in some detail the arrangements which would be required for supplying this parish with a sufficient amount of the electric light. The number of incandescent lights required for a house of moderate dimensions might be taken as 100, the lights being from 15 to 18 candle power each. This is in effect the number of Swan lights employed by Sir William Thomson in lighting his house in Glasgow. Eleven-horse power would be required to excite this number of incandescent lights, and at this rate the parish of St. James's would require 3,018 multiplied by 11, or 33,200-horse power to work it. It might be fairly objected, however, that there are many houses in the parish much below the standard here referred to; but, on the other hand, there are 600 shops, involving larger requirements. Nor does this estimate provide for the large consumption of electric energy that would take place in lighting the 11 churches, 18 clubhouses, nine concert-halls, three theatres, besides numerous hotels, restaurants, and lecture-halls. A theatre of moderate dimensions, such as the Savoy Theatre, has been proved by experience to require 1,200 incandescent lights, representing an expenditure of 133-horse power; and about one-half that power would have to be set aside for each of the other public buildings here mentioned, constituting an aggregate of nearly 2,926-horse power. Again, this general estimate did not comprise street lighting, and to light the six and a half miles of principal streets of the parish with electric light would require, per mile, 35 arc lights of 350-candle power each. This, taken at the rate of 0·8-horse power per light, represented a further requirement of 182-horse power, making a total of 3,108-horse power, for purposes independent of house lighting, being equivalent to one horse power per inhabited house, and bringing the total requirements up to 109 lights, equal to 12-horse power per house. Dr. Siemens, however, could not agree with those who expect that gas lighting will be entirely superseded; on the contrary, he maintained that the electric light, while possessing great and peculiar advantages for lighting our principal rooms, halls, warehouses, &c., owing to its brilliancy, and more particularly to its non-interference with the healthful condition of the atmosphere, would leave ample room for the development of gas. Assuming, therefore, that the bulk of domestic lighting remains to the gas companies, and that the electric light is introduced into private houses only, at the rate of, say, 12 incandescent lights per house, the parish of St. James would have to be provided with electric energy sufficient to work (9+12) 3,018, equal to 63,378 lights, equal to 7,042-horse power effective; this is equal to about one-fourth the total lighting power required, taking into account that the total number of lights that have to be provided for a house are not all used at one and the same time. No allowance is made in this estimate for the transmission of power, which, in course of time, will form a very large application of electric energy; but considering that power will be required mostly in the daytime, when light is not needed, a material increase in the plant will not be necessary for that purpose. As a position for the engines and machines, Dr. Siemens suggested Golden-square. If the unoccupied area of the square were excavated and arched over to the present level, sufficient space would be provided. The cost of these works, including engine power and machines, might be estimated at £110,000, not including the conductors, &c. The size of the conductor is a most important consideration. Two things have to be considered—first the charge for interest on the original

cost and depreciation, and secondly the cost of the electrical energy lost by resistance. The sum of these two, as has been pointed out by Sir William Thomson, is least when the two components are equal, and thus we obtain the principle on which the size of the conductors should be calculated. Working on this principle, Dr. Siemens calculates that the proper size of conductor for the installation he is describing would be a rod of 3in. diameter. If the mean distance of the lamps from the station be assumed as 350 yards, the weight of copper used in the complete system of conductors would be nearly 168 tons, and its cost £15,120. To this must be added the cost of iron pipes, for carrying the conductors underground, and of testing boxes, and labour in placing them. Four pipes, of 10in. diameter each, would have to proceed in different directions from the central station, each containing 16 separate conductors of 1in. diameter, and separately insulated, each of them supplying a sub-district of 1,000 lights. The total cost of establishing these conductors may be taken at £37,000, which brings up the total expenditure for central station and leads to £177,000. It was assumed that the conductors would be placed underground, it being quite inadmissible, both as regards permanency and public safety and convenience, to place them above ground, within the precincts of towns. With this expenditure, the parish of St. James's could be supplied with the electric light to the extent of about 25 per cent. of the total illuminating power required. To provide a larger percentage of electric energy would increase the cost of establishment proportionately and that of conductor, nearly in the square ratio of the increase of the district, unless the loss of energy by resistance were allowed to augment instead. The statement that a conductor of such a size would be required to supply a single parish with electricity, might surprise many of the uninitiated who had heard of the suggested transmission of the energy of waterfalls over long distances by electrical means. In answering this question it had to be admitted that the transmission of electric energy of such potential (200 volts) as is admissible in private dwellings would involve conductors of impracticable dimensions, and in order to transmit electrical energy to such distances, it would be necessary to resort in the first place to an electric current of high tension. By increasing the tension from 200 to 1,200 volts the conductors might be reduced to one-sixth their area, and if we were content to lose a larger proportion of the energy obtained cheaply from a waterfall, we might effect a still greater reduction. A current of such high potential could not be introduced into houses for lighting purposes, but it could be passed through the coils of a secondary dynamo-machine, to give motion to another primary machine, producing currents of low potential to be distributed for general consumption. Or secondary batteries might be used to effect the conversion of currents of high into those of low potential, whichever means might be found the cheaper in first cost, in maintenance, and most economical of energy. It might be advisable to have several such relays of energy for great distances, the result of which would be a reduction of the size and cost of conductor at the expense of final effect, and the policy of the electrical engineer would, in such cases, have to be governed by the relative cost of the conductor, and of the power at its original source. If secondary batteries should become more permanent in their action than they are at the present time, they might be largely resorted to by consumers, to receive a charge of electrical energy during the day time, or the small hours of the night, when the central engine would be otherwise unemployed. The advantage of resorting to these means would depend upon the relative first cost, and the cost of working the secondary battery and the engine respectively. Working out on a similar scale the cost for the whole of London, and considering the amount of light which would be required in the richer and in the poorer districts, Dr. Siemens obtains the sum of £14,000,000, without any allowance for lamps or internal fittings. Going still further afield he finds that to extend the same system over the towns of Great Britain and Ireland would absorb a capital exceeding £64,000,000, to which would have to be added £16,000,000 for lamps and internal fittings, or a total capital of £80,000,000. Some might live to see this realized, but to find such an amount of capital, and, what was more important, to find the manufacturing appliances to produce work representing this value of machinery and wire, must necessarily be the result of many years of technical development. Dr. Siemens was, therefore, led to the conclusion that the applications now being made by electric light companies for provisional orders to supply electrical energy, not only to the towns of England, but to those of our colonies and abroad showed that their ambition was somewhat in excess of their power of performance. Turning then to the working charges of an establishment such as that above described, and assuming the 64,000 lights to be working for six hours a day, with coal at 20s. a ton, and the consumption 2lb. per effective horse-power per hour, this would come to about £18,000. Charges for wages, interest, depreciation, general management, &c., make a grand total annual charge of £41,000, or at the rate of 12s. 9½d. per incandescent lamp per annum. The cost of renewing lamps brings up the charge for each lamp to 21s. 9½d. for a year. The cost of burning gas in a good Argand burner, which would produce the same luminous effect, would be 29s., so that there is an evident balance of cheapness in favour of electric lighting. On the other hand the cost of establishing gas works would not exceed £80,000 as compared with £177,000 for electric light, so that it appears that, while it would be more costly to establish a given supply of luminous power by electricity than by gas, the former has the advantage as regards current cost of production. These calculations, however, being only based upon the present prices of gas, and not allowing for the large dividends paid by gas companies, cannot be looked upon as representing a permanent state of things. On the other hand, it is probable that electric lighting would be cheapened by resort to a larger extent to arc lights, and also by future improvements in the manufacture of incandescent lamps. Considering the two great sources for public lighting, Dr. Siemens came to the conclusion that the introduction of the electric light, even to the full extent he contemplated, would go hand in hand with an increase in the consumption of gas, and that the consequent competition could not fail to improve the quality and cheapen the supply of both greatly to the advantage of the public. As the light of luxury electricity must win, but gas will at the same time find an increasing application for the more humble purposes of diffusing light. In conclusion Dr. Siemens confirmed the remarks he made in his address last August to the British Association as to the future of gas. He thought that by the improved arrangement of the burners nearly double the amount of luminosity might be obtained, while at the same time the character of the light itself would be improved. Further, he believed, it would be advantageous for two qualities of gas to be supplied, one for heating and one for lighting. Such a general supply of heating separately from illuminating gas, by collecting the two gases into separate holders during the process of distillation, would have the beneficial effects—(1) of giving to lighting gas a higher illuminating power; (2) of relieving our towns of their most objectionable traffic, that in coal and ashes; (3) of effecting the perfect cure of that bugbear of our winter existence—the smoke nuisance; (4) of largely increasing the production of those valuable by-products, tar and ammonia, the annual value of which already exceeds by nearly £3,000,000 that of the coal consumed in the gas works.

After the reading of the paper, which was received with much applause by the crowded meeting, the chairman presented the following medals and prizes:—

The Society's silver medal for papers read before the Society during the last session.—To Professor Silvanus Thompson, D.Sc., for his paper on "Storage of Electricity;" to J. Emerson Dowson, for his paper on "The Production and Use of Gas for Purposes of Heating and Motive Power;" to Colonel G. F. Pearson, for his paper on "The Teaching of Forestry;" to Professor Barff, M.A., for his paper on "A New Antiseptic Compound, and its application to the Preservation of Food;" to Spencer Walpole, for his paper on "The Fish Supply of London;" to George F. Deacon, for his paper on "The Constant Supply and Waste of Water;" to Captain Richard F. Burton, for his paper on "Gold on the Gold Coast;" to R. Warington, for his paper on "Some Practical Aspects of Recent Investigation in Nitrification;" to S. G. Thomas and Percy C. Gilchrist, for their paper on the "Manufacture of Steel from Phosphoric Pig-iron;" to Alexander M. Chance, for his paper on "The Recovery of Sulphur from Alkali Waste by Schaffner's Process, a record of recent results;" to James Mylne, for his paper on "Experiences of an European Zemindar (landholder) in Behar." House sanitation competition.—The Society's silver medal.—To Sir Daniel Cooper, K.C.M.G., for the sanitary arrangements of his house, 6, De Vere-gardens, Kensington, W.; to Captain Charles Andrew, for the sanitary arrangements of his house, 286, Kensington-park-road, S.E.; to G. E. [illegible], for the sanitary arrangements of his house, 100, Philbeach-gardens, Kensington, S.W. Plant Label Competition.—The prize of five guineas offered through the Society by G. F. Wilson, F.R.S.—To A. J. Alment, for his improved label for plants.

Sir Frederick Bramwell said it was his privilege, as the late chairman of the Council, to move a hearty vote of thanks to Dr. Siemens for the valuable paper which had just been read. After congratulating the society upon having secured as chairman for this year one who had, in the application of pure science to the purposes of industry, so successfully carried out in his own practice the objects of this society, Sir Frederick Bramwell remarked that they had that evening had a paper devoted almost exclusively to one of the many objects of which Dr. Siemens was thorough master. Having briefly remarked upon some of the views put forward in the paper, he suggested with regard to the comparison drawn between the price at which gas and the incandescent electric light could be supplied to the consumer that it would not have been unfair to have made comparison with the more costly lights of luxury, the wax candles or lamps which many used in their sitting-rooms who would not use gas. In concluding, Sir F. Bramwell said it was a happy thing for the society that at this its 128th meeting it should have for chairman of council one who was able to promote its objects and to aid in the development of the arts and manufactures of this country (Cheers.)

Lord A. Churchill, in seconding the motion, remarked that he thought there was nothing in the papers which need place their friends the gas companies in trepidation. Whatever economy might be effected in the production of electric lighting, gas would still have its uses for heating and cooking purposes.

The vote of thanks was accorded with acclamation, and Dr. Siemens, in acknowledging the compliment, said he had in his address endeavoured to trace out the conditions under which electricity and gas could be most advantageously distributed for practical purposes at the present time; and although he agreed with Sir F. Bramwell that conditions might arise which might alter greatly the principles upon which this was to be effected, yet there was a certain class of principles that were exceedingly stubborn. One could never get more than 20s. for a pound; and if any one stated that with a given expenditure of power more light could be produced than was theoretically represented in the equivalent luminous energy of that power, one had a right to doubt such a statement. Progress would be better insured by frankly bringing to the front the limits within which the electric light could now be produced. Having made some observations on the use of gas engines, which, valuable machines as they were, yet as motors for the production of electricity for lighting purposes required to be much improved, he returned his thanks to the mover and seconder of the motion and to the meeting for their kind reception.

Electricity and Telegraphy.

The Theory of Magnetism.—Professor D. E. Hughes, F.R.S., delivered a lecture on "The Theory of Magnetism," illustrated by experiments, before the Royal Institution, on February 29. The mechanical theory of magnetism may be deemed to be the proper style and title of that brought forward by the lecturer. The phenomena of magnetism he explains by a simple rotation of the molecules of iron, as well as of all metals, nay more, of all matter, solid, liquid, gaseous, or other. All matter, according to his views, has inherent magnetic power, varying in degree in molecules of different nature, but not to any great extent. The lecturer demonstrated each portion of his theory by experiment, so that the effects were visible to the audience. The striking effects of vibration, torsion, or mechanical strain upon the destruction or creation of manifest magnetism he showed in a variety of ways, the soft iron obeying the slightest mechanical tremor, while hard iron or steel resisted the most violent treatment. The molecules of the same bar behave with extreme freedom, as in the instance of soft iron, but when a slight strain was put upon them, as when slightly bent, like an archer's bow, the bar become as rigid as steel, and mechanical action had no longer any effect. A detailed account was given of the lecturer's researches upon the atmosphere, in the course of which he has discovered that it has a saturating point, like iron, and that it is just like iron itself. This was illustrated by striking experiments upon the magnetism of the atmosphere as compared with that of iron, and with the effects of vibrations in allowing freedom of motion to magnetic conduction in iron, by means of which a magnetic pole was pushed forward to four times its previous distance. Heat and electricity produced like effects, whence Professor Hughes drew the conclusion that these three forces, each allowing molecular freedom when frictional resistance is lessened, must have a like origin, and that electrical currents can be fairly classed with heat as a mode of motion. When a bar of soft iron is strongly magnetised, as in the instance of an electro-magnet, it returns, like a spring, to a neutral state upon the cessation of the inducing force. This well-known fact has long remained a mystery. All theories of magnetism up to the present time supposed that the molecules became, on the removal of the induced current, mixed or heterogeneous. Professor Hughes believes he has made a great discovery in having solved this problem, leaving no mystery any longer, as the demonstration which he will bring forward this week before the Royal Society will reduce the matter within the domain of absolute fact. He proved his case before his audience at the Royal Institution in a less formal way, but quite as effectually, rendering a bar of iron sensibly neutral or polarised at will by simply turning it upside down. The mechanical inertia of the molecules was demonstrated by magnetising a bar, and then changing its polarity by the earth's influence alone. The inertia of magnetism and of electricity was illustrated by two bars of diverse hardness. Having dealt with other points of great interest, the lecturer concluded by saying that scientific men are agreed that heat is a mode of motion, and that the molecules of the most solid bar of iron can move in a certain space with comparative freedom, the oscillations being greatly increased with every rise in temperature. If, as already well known, the molecules can move in all planes, then there could be no valid objection to the idea of their rotation, in fact they were known to rotate in the act of crystallisation. Thus, according to Professor Hughes, magnetism is an endowment of every atom of matter.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

229 BROADWAY, NEW YORK.

P. O. Box 0888.

SATURDAY, APRIL 23, 1881.

The growth of abstract science in this country is perhaps no better illustrated than by the advance which has been made of late years in the various departments of mathematics. It is only a few years since Prof. Peirce was about the only person in the United States who held a position among the original mathematicians of the world, while to-day there are in this country a number of persons whose writings are destined to rank among the classics, and a journal of mathematics of the highest rank is published under the auspices of the Johns Hopkins University and sustained almost entirely by American contributors. Among the best of the abstract writers referred to is Mr. William Ferrel, who has been hitherto best known by his tidal researches, but is now engaged in investigations on the mathematical principles of meteorology. His latest work, just published by the Coast Survey, is now before us, and although nominally consisting only of researches on Cyclones, Waterspouts and Tornadoes, is in reality a valuable contribution to the theory of storms in general.

The Board of Directors of the Ohio Mechanics' Institute have organized a "*Department of Science and Arts*" for the purpose of increasing the usefulness of the Institution. A Section of Mechanics and Engineering under the chairmanship of Professor H. T. Eddy, and one of Chemistry under Professor F. W. Clark, have been arranged. Meetings for the public discussion of scientific subjects will be held once a month, and various other arrangements are in progress which will contribute to the success of the present attempt to provide increased facilities for technical and scientific education for the youths of Cincinnati.

SCIENTIFIC SOCIETIES OF WASHINGTON.

The Biological Society, Washington.—Since our last report the following papers have been read: "Roan Mountain, North Carolina, and its Flora," by Prof. J. W. Chickering, Jr.; "Notes on the Flowering of *Solanum rostratum* and Cassia chamaecrista, with illustrations," by Prof. J. E. Todd; "A Critical Review of Günther's Ichthyology," by Prof. Theodore Gill; "On the Mortality of Marine Animals in the Gulf of Mexico," by Mr. Ernst Ingersoll: "A Statistical View of the Flora of the District of Columbia," by Prof. Lester F. Ward. It is to be regretted that the absence of our Washington correspondent from the meetings deprives us of abstracts of these valuable papers.

The Anthropological Society.—The Constitution of this society, now in its third year, makes it obligatory upon the President to prepare at the commencement of each year, a summary of the transactions of the organization during the past year. At the close of the first year, the President overlooked this fact, but made ample amends at the commencement of the third year by preparing a pamphlet containing both annual addresses, and copious abstracts of all the papers that had ever been read.

Since our last report, the following papers have been read: "The Savage Mind in the Presence of Civilization," by Prof. Otis T. Mason; "Prehistoric Trephining," by Dr. Robert Fletcher; "Some Superstitions of the Sioux Indians," by Dr. H. Yarrow; "The Chief's Son and the Thunders: An Omaha Myth," by Rev. J. Owen Dorsey.

The design of the first named paper was two-fold: first, to show that the presence of other peoples better furnished and skilled in some respect had always operated as a stimulus in the onward march of civilization; and second to draw attention to the fact that in the treatment of the Indians, Chinese, and Negroes, the phenomena of the past history of civilization were being re-presented. The two latter papers were recitals of exceedingly interesting Indian myths. Dr. Fletcher, who is associated with Dr. Billings in publishing "Index Medicus," having collected all that could be gathered on the subject of prehistoric-trephining, from two years reading, gave an elaborate summary of his investigations.

The Philosophical Society of Washington.—The Spectrophone.—At the 198th meeting of the Philosophical Society of Washington, Prof. Alexander Graham Bell communicated the announcement of his discovery of the Spectrophone, the latest outgrowth of the Photophone.

In a paper read before the American Association for the Advancement of Science, in which he announced the discovery of the photophone, Mr. Bell ventured the prediction that probably all matter would be found to posses sonorous properties of the same nature as those manifested by the discs used in that instrument. More recent investigations in Europe with gases and liquids have fully verified this prediction. Any liquid or gas placed in a test tube and exposed to the action of a beam of light condensed upon it by a lens can be made, by means of an interrupter, to emit musical tones. This has been shown by Prof. Tyndall in his memoir, to the Royal Society, on Radiant Heat. Some substances thus emit feeble sounds, others stronger ones. Iodine vapor, Nitrogen Oxide and Bromine give very loud sounds. It is found that those substances which emit loud sounds are those which absorb heat in a high degree, and among these lamp-black is especially remarkable. It has been questioned whether such sounds are provoked by the luminous rays or by the dark ones. M. Mercadier expressed the belief that the inciting rays are the red and dark ones. This led Mr. Bell, with the assistance of Mr. Sumner Tainter, to experiment with the sonorous properties of Carbon Disulphide, actuated by the light of the Spectrum.

When lamp-black is exposed to the action of the light of the spectrum it is found to give a sonorous response to all of its rays as far as the middle of the violet, and perhaps beyond. The intensity of the sound, however, varies remarkably in different parts of the spectrum. Taking the rays successively from different parts, from the violet towards the red, the sounds begin very feebly and increase in intensity, reaching a maximum in the ultra red. Beyond that point they suddenly cease. The increase of intensity is very gradual, the decrease very sudden.

Other substances have been experimented with, and while exhibiting similar properties, each has a range of its own. Porous and fibrous substances give loud sounds. Thus, common wool or worsted are found to be very sonorous, but the sounds are obtained wholly from the visible parts of the spectrum and have the maximum intensity in the green. In all substances tried success has resulted, but nearly all have a very short range.

In experimenting with more homogeneous substances of simpler constitution, still more definite results are obtained. The rays of the spectrum are passed through sulphuric ether. Outside of the ultra red is a very narrow band which cause sounds while the other parts fail to produce them. Hydrogen peroxide gives sounds at several places wholly within the visible parts of the spectrum, and these places are found to coincide with the positions of the known absorption bands of that substance. The same is found to be true of Nitrogen Oxide and a solution of Ammonia, Sulphate of Copper, and many other substances. The general law deduced is that *sounds are produced in any substance by the rays which it absorbs.*

Thus a kind of spectrum analysis can be obtained through the intermediation of sound. The principal value of the spectrophone, Mr. Bell believes, will be found in the investigation of absorption bands in the ultra red part of the spectrum.

Mr. William B. Taylor inquired whether the sounds observed from the two absorption bands of ammonia, sulphate of copper, were octaves. Mr. Bell replied that this question had not as yet been investigated.

Mr. G. Brown Goode read portions of a paper on the sword-fish and its allies, which paper will be published in full in the next annual report of the U. S. Fish Commission.

ON THE MODERN DEVELOPMENT OF FARADAY'S CONCEPTION OF ELECTRICITY.*

By Professor Helmholtz.

The majority of Faraday's own researches were connected, directly or indirectly, with questions regarding the nature of electricity, and his most important and most renowned discoveries lay in this field. The facts which he has found are universally known. Nevertheless, the fundamental conceptions by which Faraday has been led to these much-admired discoveries have not been received with much consideration. His principal aim was to express in his new conceptions only facts, with the least possible use of hypothetical substances and forces. This was really a progress in general scientific method, destined to purify science from the last remnants of metaphysics. Now that the mathematical interpretations of Faraday's conceptions regarding the nature of electric and magnetic force has been given by Clerk Maxwell, we see how great a degree of exactness and precision was really hidden behind his words, which to his contemporaries appeared so vague or obscure; and it is astonishing in the highest to see what a large number of general theorems the methodical deduction of which requires the highest powers of mathematical analysis, he has found by a kind of intuition, with the security of instinct, without the help of a single mathematical formula.

The electrical researches of Faraday, although embracing a great number of apparently minute and disconnected questions, all of which he has treated with the same careful attention and conscientiousness, are really always aiming at two fundamental problems of natural philosophy, the one more regarding the nature of physical forces, or of forces working at a distance; the other, in the same way, regarding chemical forces, or those which act from molecule to molecule, and the relation between these and the first.

The great fundamental problem which Faraday called up anew for discussion was the existence of forces working directly at a distance without any intervening medium. During the last and the beginning of the present century the model after the likeness of which nearly all physical theories had been formed was the force of gravitation acting between the sun, the planets, and their satellites. It is known how, with much caution and even reluctance, Sir Isaac Newton himself proposed his grand hypothesis, which was destined to become the first great and imposing example, illustrating the power of true scientific method.

But then came Oerstedt's discovery of the motions of magnets under the influence of electric currents. The force acting in these phenomena had a new and very singular character. It seemed as if it would drive a single isolated pole of a magnet in a circle around the wire conducting the current, on and on without end, never coming to rest. Faraday saw that a motion of this kind could not be produced by any force of attraction or repulsion, working from point to point. If the current is able to increase the velocity of the magnet, the magnet must react on the current. So he made the experiment, and discovered induced currents; he traced them out through all the various conditions under which they ought to appear. He concluded that somewhere in a part of the space traversed by magnetic force there exists a peculiar state of tension, and that every change of this tension produces electromotive force. This unknown hypothetical state he called provisionally the electrotonic state, and he was occupied for years and years in finding out what was this electrotonic state. He discovered at first, in 1838, the dielectric polarisation of electric insulators, subject to electric forces. Such bodies show, under the influence of electric forces, phenomena perfectly analogous to those exhibited by soft iron under the influence of the magnetic force. Eleven years later, in 1849, he was able to demonstrate that all ponderable matter is magnetized under the influence of sufficiently intense magnetic force, and at the same time he discovered the phenomena of diamagnetism, which indicated that even space, devoid of all ponderable matter, is magnetizable; and now with quite a wonderful sagacity and intellectual precision Faraday performed in his brain the work of a great mathematician without using a single mathematical formula. He saw with his mind's eye that by these systems of tensions and pressures produced by the dielectric and magnetic polarisation of space which surrounds electrified bodies, magnets or wires conducting electric currents, all the phenomena of electro-static, magnetic, electro-magnetic attraction, repulsion, and induction could be explained, without referring at all to forces acting directly at a distance. This was the part of his path where so few could follow him; perhaps a Clerk Maxwell, a second man of the same power and independence of intellect, was necessary to reconstruct in the normal methods of science the great building, the plan of which Faraday had conceived in his mind and attempted to make visible to his contemporaries.

Nevertheless the adherents of direct action at a distance have not yet ceased to search for solutions of the electro-magnetic problem. The present development of science, however, shows, as I think, a state of things very favorable to the hope that Faraday's fundamental conceptions may in the immediate future receive general assent. His theory, indeed, is the only existing one which is at the same time in perfect harmony with the facts observed, and which at least does not lead into any contradiction against the general axioms of dynamics.

It is not at all necessary to accept any definite opinion about the ultimate nature of the agent which we call electricity.

Faraday himself avoided as much as he could giving any affirmative assertion regarding this problem, although he did not conceal his disinclination to believe in the existence of two opposite electric fluids.

For our own discussion of the electro-chemical phenomena, to which we shall turn now, I beg permission to use the language of the old dualistic theory, because we shall have to speak principally on relations of quantity.

I now turn to the second fundamental problem aimed at by Faraday, the connection between electric and chemical force. Already, before Faraday went to work, an elaborate electro-chemical theory had been established by the renowned Swedish chemist, Berzelius, which formed the connecting-link of the great work of his life, the systematisation of the chemical knowledge of his time. His starting point was the series into which Volta had arranged the metals according to the electric tension which they exhibit after contact with each other, a fundamental point which Faraday's experiment contradicted with the supposition that the quantity of electricity collected in each atom was dependent on their mutual electro-chemical differences, which be considered as the cause of their apparently greater chemical affinity. But although the fundamental conceptions of Berzelius's theory have been forsaken, chemists have not ceased to speak of positive and negative constituents of a compound body. Nobody can overlook that such a contrast of qualities, as was expressed in Berzelius's theory, really exists, well developed at the extremities, less evident in the middle terms of the series, playing an important part in all chemical actions, although often subordinated to other influences.

When Faraday began to study the phenomena of decomposition by the galvanic current, which of course were considered by Berzelius as one of the firmest supports of his theory, he put a very simple question; the first question, indeed, which every chemist speculating about electrolysis ought to have answered. He asked, What is the quantity of electrolytic decomposition if the same quantity of electricity is sent through several electrolytic cells? By this investigation he discovered that most important law, generally known under his name, but called by him the law of definite electrolytic action.

Faraday concluded from his experiments that a definite quantity of electricity cannot pass a voltametric cell containing acidulated water between electrodes of platinum without setting free at the negative electrode a corresponding definite amount of hydrogen, and at the positive electrode the equivalent quantity of oxygen, one atom of oxygen for every pair of atoms of hydrogen. If instead of hydrogen any other element capable of substituting hydrogen is separated from the electrolyte, this is done also in a quantity exactly equivalent to the quantity of hydrogen which would have been evolved by the same electric current.

Since that time our experimental methods and our knowledge of the laws of electrical phenomena have made enormous progress, and a great many obstacles have now been removed which entangled every one of Faraday's steps, and obliged him to fight with the confused ideas and ill-applied theoretical conceptions of some of his contemporaries. We need not hesitate to say that the more experimental methods were refined, the more the exactness and generality of Faraday's law was confirmed.

In the beginning Berzelius and the adherents of Volta's original theory of galvanism, based on the effects of metallic contact, raised many objections against Faraday's law. By the combination of Nobili's astatic pairs of magnetic needles with Schweigger's multiplicator, a coil of copper wire with numerous circumvolutions, galvanometers became so delicate that the electro-chemical equivalent of the smaller currents they indicated was imperceptible for all chemical methods. With the newest galvanometers you can very well observe currents which would want to last a century before decomposing one milligram of water, the smallest quantity which is usually weighed on chemical balances. You see that if such a current lasts only some seconds or some minutes, there is not the slightest hope to discover its products of decomposition by chemical analysis. And even if it should last a long time the feeble quantities of hydrogen collected at the negative electrode can vanish, because they combine with the traces of atmospheric oxygen absorbed by the liquid. Under such conditions a feeble current may continue as long as you like without producing any visible trace of electrolysis, even not of galvanic polarisation, the appearance of which can be used as an indication of previous electrolysis. Galvanic polarisation, as you know, is an altered state of the metallic plates which have been used as electrodes during the decomposition of an electrolyte. Polarised electrodes, when connected by a galvanometer, give a current which they did not give before being polarised. By this current the plates are discharged again and returned to their original state of equality.

This depolarising current is indeed a most delicate means of discovering previous decomposition. I have really ascertained that under favorable conditions one can observe the polarisation produced during some seconds by a current which decomposes one milligram of water in a century.

Products of decomposition cannot appear at the electrodes without motions of the constituent molecules of the electrolyte throughout the whole length of the liquid. This subject has been studied very carefully, and for a great number of liquids, by Prof. Hittorff, of Münster, and Prof. G. Wiedemann, of Leipsic.

Prof. F. Kohlrausch, of Wurzburg, has brought to light the very important fact that in diluted solutions of salts, including hydrates of acids and hydrates of caustic alkalies, every atom under the influence of currents of the same density moves on with its own peculiar velocity, independently of other atoms moving at the same time in the same or in opposite directions. The total amount of chemical motion in every section of the fluid is represented by the sum of the equivalents of the cation gone forwards and of the anion gone backwards, in the same way as in the dualistic theory of electricity, and the total amount of electricity flowing through a section of the conductor corresponds to the sum of positive electricity going forwards and negative electricity going backwards.

This established, Faraday's law tells us that through each section of an electrolytic conductor we have always equivalent electrical and chemical motion. The same definite quantity of either positive or negative electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion, and accompanies it during all its motions through the interior of the electrolytic fluid. This we may call the electric charge of the atom.

Now the most startling result, perhaps, of Faraday's law is this: If we accept the hypothesis that the elementary substances are composed of atoms we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity. As long as it moves about on the electrolytic liquid each atom remains united

* The Faraday Lecture, delivered before the Fellows of the Chemical Society in the Theatre of the Royal Institution, on Tuesday, April 5th, 1881, by Professor Helmholtz. Abstract revised by the author.

45

42-44

with its electric equivalent or equivalents. At the surface of the electrodes decomposition can take place if there is sufficient electromotive power, and then the atoms give off their electric charges and become electrically neutral.

Now arises the question, Are all these relations between electricity and chemical combination limited to that class of bodies which we know as electrolytes? In order to produce a current of sufficient strength to collect enough of the products of decomposition without producing too much heat in the electrolyte, the substance which we try to decompose ought not to have too much resistance against the current. But this resistance may be very great, and the motion of the ions may be very slow, so slow indeed that we should need to allow it to go on for hundreds of years before we should be able to collect even traces of the products of decomposition; nevertheless all the essential attributes of the process of electrolysis could subsist. If you connect an electrified conductor with one of the electrodes of a cell filled with oil of turpentine, the other with the earth, you will find that the electricity of the conductor is discharged unmistakably more rapidly through the oil of turpentine than if you take it away and fill the cell only with air.

Also in this case we may observe polarisation of the electrodes as a symptom of previous electrolysis. Another sign of electrolytic conduction is that liquids brought between two different metals produce an electromotive force. This is never done by metals of equal temperature, or other conductors which, like metals, let electricity pass without being decomposed.

The same effect is also observed even with a great many rigid bodies, although we have very few solid bodies which allow us to observe this electrolytic conduction with the galvanometer, and even these only to temperatures near to their melting-point. It is nearly impossible to shelter the quadrants of a delicate electrometer against being charged by the insulating bodies by which they are supported.

In all the cases which I have quoted one might suspect that traces of humidity absorbed by the substance or adhering to their surface were the electrolytes. I show you therefore this little Daniell's cell, in which the porous septum has been substituted by a thin stratum of glass. Externally all is symmetrical at both poles; there is nothing in contact with the air but a closed surface of glass, through which two wires of platinum penetrate. The whole charges the electrometer exactly like a Daniell's cell of very great resistance, and this it would not do if the septum of glass did not behave like an electrolyte. All these facts show that electrolytic conduction is not at all limited to solutions of acids or salts.

Hitherto we have studied the motions of ponderable matter as well as of electricity, going on in an electrolyte. Let us study now the forces which are able to produce these motions. It has always appeared somewhat startling to everybody who knows the mighty power of chemical forces, the enormous quantity of heat and of mechanical work which they are able to produce, and who compares with it the exceedingly small electric attraction which the poles of a battery of two Daniell's cells show. Nevertheless this little apparatus is able to decompose water.

The quantity of electricity which can be conveyed by a very small quantity of hydrogen, when measured by its electrostatic forces, is exceedingly great. Faraday saw this, and has endeavored in various ways to give at least an approximate determination. The most powerful batteries of Leyden jars, discharged through a voltameter, give scarcely any visible traces of gases. At present we can give definite numbers. The result is that the electricity of 1 m.grm. of water, separated and communicated to two balls, 1 kilometre distant, would produce an attraction between them, equal to the weight of 25,000 kilos.

The total force exerted by the attraction of an electrified body upon another charged with opposite electricity is always proportional to the quantity of electricity contained in the attracting as on the attracted body, and therefore even the feeble electric tension of two Daniell's elements, acting through an electrolytic cell upon the enormous quantities of electricity with which the constituent ions of water are charged, is mighty enough to separate these elements and to keep them separated.

We now turn to investigate what motions of the ponderable molecules require the action of these forces. Let us begin with the case where the conducting liquid is surrounded everywhere by insulated bodies. Then no electricity can enter, none can go out through its surface, but positive electricity can be driven to one side, negative to the other, by the attracting and repelling forces of external electrified bodies. This process going on as well in every metallic conductor is called "electrostatic induction." Liquid conductors behave quite like metals under these conditions. Prof. Wüllner has proved that even our best insulators, exposed to electric forces for a long time, are charged at last quite in the same way as metals would be charged in an instant. There can be no doubt that even electromotive forces going down to less than 1-100 Daniell produce perfect electrical equilibrium in the interior of an electrolytic liquid.

Another somewhat modified instance of the same effects is afforded by a voltametric cell containing two electrodes of platinum, which are connected with a Daniell's cell, the electromotive force of which is insufficient to decompose the electrolyte. Under this condition the ions carried to the electrodes cannot give off their electric charges. The whole apparatus behaves, as was first accentuated by Sir W. Thomson, like a condenser of enormous capacity.

Observing the polarizing and depolarizing currents in a cell containing two electrodes of platinum, hermetically sealed and freed of all air, we can observe these phenomena with the most feeble electromotive forces of 1-1000 Daniell, and I found that down to this limit the capacity of the platinum surfaces proved to be constant. By taking greater surfaces of platinum I suppose it will be possible to reach a limit much lower than that. If any chemical force existed besides that of the electrical charges which could bind all the pairs of opposite ions together, and require any amount of work to be vanquished, an inferior limit to the electromotive forces ought to exist, which forces are able to attract the atoms to the electrodes and to charge these as condensers. No phenomenon indicating such a limit has as yet been discovered, and we must conclude, therefore, that no other force resists the motions of the ions through the interior of the liquid than the mutual attractions of their electric charges.

On the contrary, as soon as an ion is to be separated from its electrical charge we find that the electrical forces of the battery meet with a powerful resistance, the overpowering of which requires a good deal of work to be done. Usually the ions, losing their electric charges, are separated at the same time from the liquid; some of them are evolved as gases, others are deposited as rigid strata on the surface of the electrodes, like galvanoplastic copper. But the union of two constituents having powerful affinity to form a chemical compound, as you know very well, produces always a great amount of heat, and heat is equivalent to work. On the contrary, decomposition of the compound substances requires work, because it restores the energy of the chemical forces, which has been spent by the act of combination.

Metals uniting with oxygen or halogens produce heat in the same way, some of them, like potassium, sodium, zinc, even more heat than an equivalent quantity of hydrogen; less oxidisible metals, like copper, silver, platinum, less. We find, therefore, that heat is generated when zinc drives copper out of its combination with the compound halogen of sulphuric acid, as is the case in a Daniell's cell.

45

If a galvanic current passes through any conductor, a metallic wire, or an electrolytic fluid, it evolves heat. Mr. Prescott Joule was the first who proved experimentally that if no other work is done by the current the total amount of heat evolved in a galvanic circuit during a certain time is exactly equal to that which ought to have been generated by the chemical actions which have been performed during that time. But this heat is not evolved at the surface of the electrodes, where these chemical actions take place, but it is evolved in all the parts of the circuit, proportionally to the galvanic resistance of every part. From this it is evident that the heat evolved is an immediate effect, not of the chemical action, but of the galvanic current, and that the chemical work of the battery has been spent in producing only the electric action.

If we apply Faraday's law, a definite amount of electricity passing through the circuit corresponds to a definite amount of chemical decomposition going on in every electrolytic cell of the same circuit. According to the theory of electricity the work done by such a definite quantity of electricity which passes, producing a current, is proportionate to the electromotive force acting between both ends of the conductor. You see, therefore, that the electromotive force of a galvanic circuit must be, and is, indeed, proportionate to the heat generated by the sum of all the chemical actions going on in all the electrolytic cells during the passage of the same quantity of electricity. In cells of the galvanic battery chemical forces are brought into action able to produce work; in cells in which decomposition is occurring work must be done against opposing chemical forces; the rest of the work done appears as heat evolved by the current, as far as it is not used up to produce motions of magnets or other equivalents of work.

Hitherto we have supposed that the ion with its electric charge is separated from the fluid. But the ponderable atoms can give off their electricity to the electrode, and remain in the liquid, being now electrically neutral. This makes almost no difference in the value of the electromotive force. For instance, if chlorine is separated at the anode, it will remain at first absorbed by the liquid; if the solution becomes saturated, or if we make a vacuum over the liquid, the gas will rise in bubbles. The electromotive power remains unaltered. The same may be observed with all the other gases. You see in this case that the change of electrically negative chlorine into neutral chlorine is the process which requires so great an amount of work, even if the ponderable matter of the atoms remains where it was.

The more the surface of the positive electrode is covered with negative atoms of the anion, and the negative with the positive ones of the cation, the more the attracting force of the electrodes exerted upon the ions of the liquid is diminished by this second stratum of opposite electricity covering them. On the contrary, the force with which the positive electricity of an atom of hydrogen is attracted towards the negatively charged metal increases in proportion as more negative electricity collects before it on the metal, and the more negative electricity collects behind it in the fluid.

Such is the mechanism by which electric force is concentrated and increased in its intensity to such a degree that it becomes able to overpower the mightiest chemical affinities we know of. If this can be done by a polarized surface, acting like a condenser, charged by a very moderate electromotive force, can the attractions between the enormous electric charges of anions and cations play an unimportant and indifferent part in chemical affinity?

You see, therefore, if we use the language of the dualistic theory and treat positive and negative electricities as two substances, the phenomena are the same as if equivalents of positive and negative electricity were attracted by different atoms, and perhaps also by the different values of affinity belonging to the same atom with different force. Potassium, sodium, zinc, must have strong attraction to a positive charge; oxygen, chlorine, bromine to a negative charge.

Faraday very often recurs to this to express his conviction that the forces termed chemical affinity and electricity are one and the same. I have endeavored to give you a survey of the facts in their mutual connection, avoiding, as far as possible, introducing other hypotheses, except the atomic theory of modern chemistry. I think the facts leave no doubt that the very mightiest among the chemical forces are of electric origin. The atoms cling to their electric charges and the opposite electric charges cling to the atoms. But I don't suppose that other molecular forces are excluded, working directly from atom to atom. Several of our leading chemists have begun lately to distinguish two classes of compounds, molecular aggregates and typical compounds. The latter are united by atomic affinities, the former not. Electrolytes belong to the latter class.

If we conclude from the facts that every unit of affinity of every atom is charged always with one equivalent either of positive or of negative electricity, they can form compounds, being electrically neutral, only if every unit charged positively unites under the influence of a mighty electric attraction with another unit charged negatively. You see that this ought to produce compounds in which every unit of affinity of every atom is connected with one and only with one other unit of another atom. This is, as you will see immediately, indeed, the modern chemical theory of quantivalence, comprising all the saturated compounds. The fact that even elementary substances, with few exceptions, have molecules composed of two atoms, makes it probable that even in these cases electric neutralization is produced by the combination of two atoms, each charged with its electric equivalent, not by neutralization of every single unit of affinity.

But I abstain from entering into mere specialties, as for instance, the question of unsaturated compounds; perhaps I have gone already too far. I would not have dared to do it if I did not feel myself sheltered by the authority of that great man who was guided by a never-erring instinct of truth. I thought that the best I could do for his memory was to recall to the minds of the men, by the energy and intelligence of whom chemistry has undergone its modern astonishing development, what important treasures of knowledge lie still hidden in the works of that wonderful genius. I am not sufficiently acquainted with chemistry to be confident that I have given the right interpretation, that interpretation which Faraday himself would have given perhaps, if he had known the law of chemical quantivalence, if he had had the experimental means of ascertaining how large the extent, how unexceptional the accuracy of his law really is; and if he had known the precise formulation of the law of energy applied to chemical work, and of the laws which determine the distribution of electric forces in space as well as in ponderable bodies transmitting electric current or forming condensers. I shall consider my work of to-day well rewarded if I have succeeded in kindling anew the interest of chemists for the electro-chemical part of their science.

MANUFACTURE OF SODA FROM SULPHATE.—Salt-cake is produced in quantity in California in the manufacture of nitric acid. As coal and lime-stone are dear in California, Le Blanc's process is not economical. The author therefore proposes to mix a solution of salt cake with calcium sulphite and pass in sulphurous acid. Soluble calcium bisulphite is formed, and by decomposition calcium sulphate and sodium bisulphite. The two salts are separated by filtration, and the sodium bisulphite is treated with milk of lime. The result is a solution of caustic soda, retaining a certain quantity of sodium sulphite and sulphate, which is evaporated down in the usual manner, and calcium sulphite, which is used again in the process.—J. PUTZKOW.

Engineering July 1881.

MOLECULAR MAGNETISM.

ON a former occasion (see page 388 of our last volume) we gave an account of the principal results of Professor Hughes' latest experiments on the essential nature of magnetism and electricity, and we have now to give some supplementary facts which he has observed more recently, and embodied in a communication to the Royal Society. These facts may all be regarded as fresh evidence in favour of the molecular theory of magnetism, and antagonistic to the fluid theory of electricity.

In his previous researches Professor Hughes demonstrated that an electric current could be produced in an iron wire when under the influence of magnetism if it were twisted, that is subjected to a torsional stress, and conversely he showed that if an electric current is sent through an iron wire while it is magnetised, it experiences a molecular twist. The magnetism of the wire may be produced in several ways; by a permanent magnet held near the wire; by the magnetic medium surrounding a coil traversed by a current, illustrated in Fig. 1 of our former article, and by the magnetic field of the earth itself. In the latter case the iron wire should lie along the direction of the earth's lines of magnetic force and not at right angles to them, else there will be no effect. But the passage of an electric current through the wire also produces this magnetic condition very strongly, and Professor Hughes now finds that he is unable to restore the wire by means of mechanical stress exactly to its original non-magnetic state after the current passes. The magnetism produced by the passage of the current is far more powerful and persistent in soft iron than tempered steel. Only wire of a magnetic metal will give these results, and it must also contain at least a trace of magnetism, whether produced by the influence of a magnet or an electric current. In short, all the effects obtained by Professor Hughes in these present experiments are due, in some way, to the magnetisation of the wire. The torsion currents are best observed by twisting the wire to right and left by a see-saw movement, and listening to them in a telephone, whose circuit is interrupted by a rheotome, or watching the oscillation of a galvanometer needle swinging in time with the torsional movement. At the moment of reversing the torsion a peculiar click is heard, which Professor Hughes attributes to a sudden change in the polarity of the iron molecules. This click is heard equally well with an iron or a steel wire, but the after-currents are very much weaker in the case of steel, a result which may mean that while the polarisation of the molecules is equally strong in both iron and steel, the rigidity of the steel molecules prevents their being turned round by the torsion. Thus, if the iron wire be permanently twisted it behaves in some degree like rigid steel.

We have said that the magnetism produced in the wire by the passage of a current through it is, unlike that due to the touch of a permanent magnet, very difficult to get rid of by stress; but Professor Hughes finds that it can be cleared away either by heating the wire red hot, or stroking it with a magnet. This curious fact is explained by the hypothesis that the passage of the current produces a transverse or radial polarity of the molecules, which is difficult to alter by torsional stress, whereas the touch of the magnet changes it into a longitudinal polarity which can readily be disturbed.

The supposed spiral path of the current in the wire was next investigated by Professor Hughes, who has verified the celebrated experiment of De la Rive for solid conductors as well as vacuo. De la Rive showed that an electric current in a vacuum tube travels a spiral path round a magnet, and in a direction depending on the pole of the magnet presented to the current. Professor Hughes shows that a current traverses a magnetised steel wire in a spiral path; if the current is positive and enters at the north pole the spiral is right-handed; if it is negative entering the same pole the spiral is left-handed.

It is further remarkable that if while a current is traversing the wire, the latter is magnetised by the stroking of a permanent magnet, a strong disturbance takes place and the spiral path of the current appears to become fixed. For whether the current sent through it be positive or negative its path is the same as that of the current traversing its wire when it was being magnetised. Of course the direction of this permanent spiral depends on the direction of the magnetic stroke and the pole of the magnet employed, and if the stroke was made from both ends of the wire to the centre the spiral path which remains changes its direction from right to left at the middle of the wire. Heating the wire red-hot while it is being traversed by a current, and then cooling it, has also the effect of fixing for a time the spiral path of the current and determining the course of other currents whether positive or negative.

In his earlier experiments Professor Hughes succeeded in evoking distinct musical tones from a fine soft iron wire through which a current interrupted by a rhythmic rheotome was flowing. The cadence of these tones was, of course, that of the rheotome, but it is curious that the pitch is evidently independent alike of the diameter of the wire and its length and tension. Indeed, Professor Hughes is of opinion that it depends entirely on the molecular strain of the wire, a conclusion justified by several experiments which we need not repeat.

Enough, however, has been said to show the important part played by the molecular arrangement in a magnet and a conductor. It is evidently by the rotation of its polarised molecules that an electric current is generated in an iron wire by tension, and on the other hand the passage of a current in the wire apparently rotates its molecules.

47

IRON.

THE APPLICATIONS OF ELECTRICITY.*

THE second of the series of six lectures on the applications of electricity was delivered at the Institution of Civil Engineers, on March 1, by Sir Frederick Bramwell, F.R.S., V.P. Inst.C.E., the subject being "Telephones." The following is an abstract of the lecture:—

Prior to the invention of the telephone, by making and breaking circuit at the transmitting station sounds had been produced at the receiving station—such as the striking of bells, or the vibration of a Morse sounder—but these were independent of sound at the transmitting station, and they varied according to the implement used at the receiving station, and were and are used for purposes of audible telegraphy. Also, prior to the invention of the telephone, it was possible to reproduce at the receiving station, say, by a tuning-fork, the vibrations of which break and make contact, the same note produced by a similar tuning-fork at the transmitting station; and in this case there was a reproduction at the receiving station of the sound at the transmitting station. But the only thing that was ensured was the repetition of the same note—there was no reproduction of the same sound. For example, the note might have been uttered by a violin-string, by a tuning-fork, or by a clarionet at the transmitting station; at the receiving station, however, nothing would be given forth but the note of the particular tuning-fork, or other vibrating implement, which was in accord with the number of the vibrations transmitted in a given time. All these modes were due to the variations of the current caused by break and make in the circuit, and were therefore abrupt. The best result obtained with such an agency was in the machine of Reiss, who, in 1862, reproduced tones, and it is said some words were heard. That machine received no development, and telephony lay dormant for fourteen years, until the invention of Professor Graham Bell, patented in this country in December 1876. In 1874 Mr. William Henry Barlow, F.R.S., past-president Inst.C.E., turned his attention to the recording of the vibrations produced by speech. He effected this by means of an instrument called a logograph. This was communicated to the Royal Society, and exhibited in operation there. By its agency there was depicted on a travelling band of paper the motions derived from the vibration of a membrane under the influence of speech; but had the results been known they would probably have deterred an inventor seeking to produce a telephone, as it appeared the vibrations were not always the same for the same syllable, but varied with the speaker and from the circumstances. Professor Graham Bell graphically represented the variations in the electric current, either direct or reversed, caused by break and make, and showed that these were too abrupt for his purpose—namely, the reproduction of articulate speech. He proposed to attain the object sought by having the circuit always closed, and by causing rises and falls, or reversals, as the case might be, of electricity which should be made gradually, instead of abruptly, as before. The simplest mode in which he attained this end was in one of the original forms of the Bell transmitter or receiver (for the instrument was capable of fulfilling either function) by placing an iron or a steel plate in the neighbourhood of a permanent magnet surrounded by a coil of insulated wire, so that on the plate being set into vibration by the voice it should induce, in the coil, reversed currents of electricity which could travel along the wire in prolongation of the coil to the coil of the similar instrument at the receiving station, thereby varying the power of the magnet at that station and setting up vibrations in the corresponding iron disc. This disc, acting upon the air, gave to it vibrations similar to those which had put the first disc into motion, and in that way a reproduction of the original sound (as Professor Bell said, a facsimile) was obtained. Other modes were employed by him, such as the use of a battery in the line-wire, and, best of all, the use of two local batteries to send the current to a primary coil round a core, the line-wire being connected with secondary coils acting by induced electricity. As transmitters those instruments were necessarily somewhat feeble, since the whole of the electricity in the first of the three cases mentioned, and what might be called the operative electricity in the other two cases, had to be derived from the microscopic movements of the disc, under the influence of the sound-waves produced by the speaker.

Edison's phonograph was exhibited, in order to show that a disc, when caused to vibrate under speech, could by a control needle impress those vibrations on tin foil, and that on the tin foil being caused to traverse under the needle, the reproduction on the disc of those vibrations caused it to repeat the speech which had originally set the disc in motion. This was appealed to as a convincing proof that a disc, when mechanically vibrated in a manner corresponding to the vibrations which had been imparted to it by speech was sufficient, wholly irrespective of any electrical agency, to impress upon the air the needful vibrations to reproduce speech. Edison then devised a transmitter, wherein the disc need not be metallic, but might be mica, and its vibrations were caused to operate upon a small block of carbon, which carbon was introduced in the circuit of a battery. It was thus found that the almost inappreciable variation in pressure due to the vibration of the disc was sufficient, for some not very well understood reason, to alter the conducting power of the carbon, and to cause varying currents to be transmitted along the line-wire to the Bell receiver at the opposite end. At the present day the universal transmitting instrument for commercial purposes is the carbon transmitter of Edison or some modification thereof. Professor Hughes's microphone was next alluded to, and it was stated how by its means the most minute sounds were rendered audible, and how, from the delicacy of the instrument, it is applicable to many scientific purposes. Edison's chalk receiver was subsequently explained. Prior to Edison's time, it had been known that the friction of certain surfaces varied with the electric current passing through them, notably under such circumstances the friction of the human tissue. Among other appropriate substances prepared chalk was one, and it was shown how Edison availed himself of this. By attaching a stem to the centre of the disc, and pressing this stem by means of an adjustable pressure upon the periphery of a chalk cylinder, a current of electricity passed from the centre of the cylinder through the stem. Upon the cylinder being turned by hand the friction on the stem caused it to move the centre of the disc—its edge being fixed—to a definite position depending on the friction, and on the rigidity of the disc; but, on a variation in the current, the change produced thereby in the friction caused the stem either to be drawn in further or to yield to the elasticity of the disc and to allow it to be moved backwards. In this manner vibrations were set up in the disc corresponding with the vibrations of the transmitter that had sent the varying electrical currents. As in the case of this receiver the power was derived, not from the electricity, but from the hand of the operator turning the chalk cylinder, very considerable loudness was obtained, so that the utterances of the receiver were audible in a large room. Mr. Shelford Bidwell having lent a photophone, that beautiful invention of Professor Graham Bell was explained. Mr Bidwell showed how, by speaking to a disc, the front being a mirror on which a powerful light was directed, that light could be reflected on to a selenium cell, and as the disc vibrated under the influence of the voice the light playing on the selenium cell varied. Selenium was a material the conductivity of which changed with the amount of light upon it. It was therefore possible in this manner to cause a Bell receiver to speak, and reproduce the speech which had been uttered to the mirror disc. It was pointed out that, in this manner, there was no need of a wire connection between the transmitter and the receiver, the passage of a beam of light being all that was required.

Reference was then made to the various purposes to which the telephone might be put, and to the exchange system and the necessary apparatus for receiving the calls and making the connections between the different subscribers to the exchange. Amongst special uses, a very interesting one was shown—that of the application of telephony to the diver's helmet. Thanks to the kindness of the captain of the H.M.S. *Vernon* and of Mr. Gorman, a helmet with the whole of the apparatus was exhibited. It was shown how the application of the telephone in no way introduced any complication, as the single wire needed was in the middle of the old call-rope the return being made by the water itself. Thus, if the telephone went wrong, the diver was left without additional apparatus of any kind to encumber him, and yet with all the resources that he would have had in the absence of the telephone. It was stated that the development of the telephone had been far more rapid in America than in England. As an instance it was mentioned that in the city of Washington, with a population of about 120,000 white persons, as many as 800 telephones were used. Then, a return, circulated that very day by the United Telephone Company, was read, showing that on February 28 in 1881 there were, independent of private lines, 845 subscribers to the London exchange; that on the same day in 1882 the number had increased to 1,505—or an addition of 660; and on February 28 this year the number was 2,541, or an addition of 1,036; and that contemporaneously with these increases the use of the telephone by each subscriber had augmented, until it now reached more than 7½ calls per day for each subscriber, which—at a cost of £20 a year—represented only twopence a call; or, bearing in mind that each call involved a return message, it only amounted to one penny for the message sent each way.

The lecturer had the assistance of Mr. E. H. Johnson, who had been so much associated with Mr. Edison in carrying out many of his inventions, and who put into work both the phonograph and the chalk receiver.

48 The Iron Age — Dec. 18, 1884.

Electrical Units and Nomenclature.

BY JOHN W. NYSTROM.

We take the following from *Mechanics* for December:

The notation of electrical quantities will herein be the same as those in the preceding article, page 257, namely: F = electromotive force. V = velocity or intensity of current in Ampères. T = time in seconds. P = power. K = work. R = resistance in ohms, and S = linear space in meters or 1000 kilometers.

UNIT-AMPERE.

It is stated by the Electrical Congress that "the Ampère is represented by that quantity of current which is capable of depositing 4.025 grams of silver per hour, or 0.001118 grams per second."

The depositing of silver or any other metal by electric currents is work, which is accomplished by the product of the three simple physical elements, *force*, *velocity* and *time*. $K = F V T$. No work can be done and no metal can be deposited without any one of these three simple elements. It is, therefore, not correct to say that "so much metal can be deposited per Ampère." When F and T are constant and the Ampère V varies, the quantity of metal deposited will be proportionate to the Ampère, but the work is still $K = F V T$. If V and T are constant and the electro-motive force varies, then the weight of metal deposited will be proportionate to the electro-motive force F, and the work will be the same, namely, $K = F V T$.

UNIT COLOMB.

The Electrical Congress says "the Colomb is the unit of dynamic quantity, and its value corresponds with that of the Ampère."

Dynamics is the name of the science of forces in motion, producing power and work, which name cannot be measured by quantity. It is evident from the drift of their vague explanations that Colomb is intended to mean quantity of electricity, which is work, $K = F V T$, which cannot correspond or compare with one of its elements, Ampères. The Colomb can be measured, or expressed by the weight of metal deposited by a current.

UNIT FARAD.

They say that "Farad is the unit of capacity, which value is equal to 1 colomb divided by 1 Volt." If Colomb means quantity of electricity, which is work, $K = F V T$, and this work divided by the electro motive force F, then the Farad becomes $S = V T$, which is linear space.

It is stated that a Farad represents a length of 5,600,000 kilometers, and a microfarad 5.6 kilometers. It appears to me that it is intended that Farad should mean the quantity of static electricity contained in a definite conductor, which quantity is $K = F V T$, and that this work should be proportionate to the volume of the conductor multiplied by the electro-motive force. If I am wrong in this, I beg to be corrected.

It would be well to establish regular units and nomenclature of quantities of electricity, based upon the metric system corresponding with mechanic-work, namely, the main standard of quantity should be that quantity which represents the work of one kilogrammeter. The two sub-units should be grammeter and milligrammeter.

For distinction in the application of these terms to quantities of electricity it would be well to abbreviate them as follows:

Kramet for kilogrammeter.
Gramet for grammeter.
Milgramet for milligrammeter.

UNIT OF LIGHT.

Light is power, and therefore the standard unit of light should correspond to one unit of power, namely, *effect*.

One electric arc light is a power of about 50 effects, and they are about 40-candle power per effect, as realized by electric currents.

The power of a light should always be expressed in effects. In my "Elements of Mechanics," published in 1875, it is explained on page 285 that "light is power, which is the product of force and velocity." Was such an explanation of light ever made prior to the year 1875?

UNIT DYNE.

In my last article I made a mistake in stating (page 236) that "the dyne is 0.98 of the milligram." It is the other way, namely, the milligram is 0.98 of a dyne. I am not sorry for having made this mistake, because it is a fair sample of the confusion of the C. G. S.

The value of the dyne is obtained in the following way: A force acting for a time of one second on a mass of one gram free to move, and give that mass a final velocity of one centimeter per second, is called one dyne.

F = the unknown force, one dyne.
W = one gram, the weight of the mass.
V = final velocity 0.01 meter per second.
g = 9.81, the acceleratrix of gravity at Paris.
T = one second, the time of action.

$$\text{Dyne } F = \frac{W V}{g T} = \frac{1 \times 0.01}{9.81 \times 1} = 0.001019 \text{ of a gram.}$$

The dyne is consequently 1.019 milligrams.

This *dyne-force* is theoretically constant in every part of the world, whether on the top of the highest mountain, on the equator or in the highest latitude; its value never changes, which is no doubt the aim of the B. A. to have such a unit of force, but this fact does not compensate for the inconvenience of not having a unit of force in electro-dynamics which corresponds with an established unit of weight. The small difference of attraction in latitude is of no practical inconvenience in mechanics, because the standard weights made in France are distributed all over the civilized world, so that a mass of matter weighing one kilogram in the highest latitude, would also weigh one kilogram on the highest mountain or the equator. With this practical consideration, the C. G. S. is a botch.

A milligram weighed in a constant latitude, say that of Paris, is as much a constant and invariable force as is the *dyne*. A minute weight in any part of the world, multiplied by the local acceleratrix and divided by the Paris acceleratrix, gives the actual weight as if weighed in Paris. When great accuracy is required the same operation must be gone through with the *dyne*, which is not 1.019 milligrams in latitudes outside of Paris.

W = weight in milligrams in any latitude outside of Paris.
g = 9.81 the acceleratrix in Paris.
G = local acceleratrix in latitude outside of that of Paris.

$$D = \frac{1.019\, W g}{G} = \frac{9.99639\, W}{G}.$$

It is to be hoped that the electricians will reject the *dyne* nuisance.

ENERGY.

I will avail myself of this opportunity to call the attention of bodies of scientific authority to the fact that the term *energy* is promiscuously used for the three distinct and different quantities, *force*, *power* and *work*. I have often noticed this indefinite use of the term *energy*, both in lectures and in books; and at a late meeting of electricians one of the party read a paper on C. G. S. units, and chalked a formula on the blackboard which represented *power*, but which he called *energy*. A little further on he chalked another formula which represented *work*, but which he also called *energy*. Another member of the party asked, "What is the reason that this formula means *energy* and that formula, which is entirely different, also means *energy*?" An evasive answer was given.

The term *energy* is generally applied to work, but my individual opinion is that it should be applied to power exclusively, for the reason that we say that Mr. A. has a great deal of energy when he accomplishes much work in a short time. If Mr. B accomplishes the same amount of work, but in a much longer time, we say that Mr. A has more energy than has Mr. B. Therefore, the popular idea of energy is power. For my part, I have no use for the term *energy*.

CONFUSION OF POWER AND WORK.

The difficulty which the B. A. has to encounter in distinguishing power from work appears to be in the application of the unit *time*. When a quantity is multiplied or divided by a unit quantity, the numerical value is not changed, but the nature of the quantity is changed. For instance, if power is multiplied by a unit of time the product will be work, while the numerical value remains unchanged. If work is divided by a unit of time the quotient becomes power, but the numerical value of that power is the same as that of the work. This is fully explained in my "Elements of Mechanics," but it appears that the B. A. is not able to take it in. I am informed by a member of that body that my ideas of dynamics have been ridiculed there.

Mr. W. H. Preece, F.R.S., complains that Professor Adams has, in a lecture, treated the power *Watt* as work. That mistake is quite common, particularly so in the B. A., and we can expect that that mistake will be continued as long as the B. A. calls power *the work done in a unit of time*.

In Holme's work on electric light, page 7[illegible] it is stated that "the electrical energy or work can be calculated by multiplying the current in Ampères by the electro-motive force in Volts. (W = C E)." He calls it *energy* or *work*, while the explanation and formula is *power*.

[illegible] of the blast upon these is quite intelligible. [B]unsen and Playfair estimated that in every cubic [m]etre of gas at a height of 2·75 feet above [the] level of the tuyere in the Alfreton furnace [th]ere were eight or ten grammes of cyanide of potassium [pe]r cubic metre of gas. Mr. Lowthian Bell's experiments [in]dicate about 4 lb. of cyanogen per ton of iron produced, [w]hich, combined with potassium, would amount in round [n]umbers to 10 lb. of the salt. The alkaline cyanides are [re]ducing agents, but whether they act with any practical [ef]fect in the furnace is still doubtful. Mr. Lowthian Bell [sa]ys, "The whole subject is one upon which my mind is by [n]o means made up." As the writer is in a similar state of [m]ind, the problem must be here left as stated, but not [so]lved.

THE SALT DEPOSITS OF MIDDLESBROUGH.

AN address on this subject was delivered by Mr. T. H. [B]ell, before the Cleveland Institution of Engineers. The [l]ecturer first traced the conditions under which salt was [fo]und in the globe. It occurred in very large quantities, [an]d was very soluble in water. He went on to give two [o]r three instances in which it occurred in solution in very [la]rge quantities, referring to the Red Sea, the Caspian Sea, [an]d the Baltic Sea. These were instanced as probable [so]urces of a future salt supply. Water would absorb 2,707 [p]arts of salt to every 10,000, or four ounces to the [g]allon. Turning to the geology of salt, he said it [w]as to be found in almost every form. It occurred [of]ten as a colourless material, but they were acquainted [w]ith it coloured with iron—of the red colour. The [sa]lt at Middlesbrough is heavily charged with nitrogen. It [co]ntained 94 per cent. of nitrogen and 4 per cent. of [o]xygen; and at Port Clarence, during the construction of [a] bore-hole, quantities of gas had bubbled up. Referring [to] an illustrated section between Stonegate and Upsall, he [st]ated that the salt of Middlesbrough belonged to a far [lo]wer series of rocks than was the case in Cheshire. Salt [oc]curred throughout Europe in beds of limited size, and [oc]casionally in great thickness, and one difficulty at [M]iddlesbrough was to ascertain the thickness and extent [of] the salt bed. Messrs. Bolckow, Vaughan & Co. had [fou]nd it, and his firm had struck it at Port Clarence; but [tha]t was all—they did not know how far it extended. The [que]stion as to whether it extended north, south, east, or [we]st was a matter upon which other people would have to [sp]end their money and take their chance. Mr. Bell [th]en touched upon the Cheshire salt deposits, and stated [th]at the apparatus used in the manufacture was very crude. [H]e believed the salt manufacturers of Middlesbrough [w]ould be shortly in a position to teach the world how to [m]ake salt. In Cheshire the salt occurred comparatively [n]ear the surface, and the water got at it, and had only to [be] pumped up in the form of brine; but at Middlesbrough [th]e deposit was at a much greater depth, and the salt was [pe]rfectly dry. Different means had, therefore, to be employed in winning it. The specific gravity of salt was [2·]205. He had estimated the quantity of salt at Middlesbrough to be about 2,000 tons per acre; therefore, [M]essrs. Bolckow, Vaughan, & Co. and Messrs. Bell [B]rothers would be able to supply some quantity [of] salt for a time to come. Water at 60 degrees [ab]sorbed 27 per cent. of salt, but with it came [a] quantity of sulphate of lime, for, when the water had [ab]sorbed all the salt it could contain, it commenced taking [up] the lime. This was extremely inconvenient to the [m]anufacturer, and the Cheshire people had tried all [m]anner of ways to get rid of it. The manufacture [ap]peared to be one of the simplest of all industries to an [ou]tsider, but it was not so. In 1857 Mr. Vaughan, [lo]oking for a supply of water for boiler purposes, sank a [bo]re-hole, and, not finding water, went on with it until [h]e came to salt. The firm turned their attention to [w]inning the salt for a time, but other things intervened, [an]d ultimately the scheme was abandoned, as it was [th]ought the expense would be too great. In 1875 Messrs. [B]ell Bros. endeavoured to find if the salt extended [ac]ross the river, and they found salt at 80 feet less [de]pth. Warned by the experience of the other firm, [h]owever, they did not care to incur the expense, and it [w]as not until Thomas Bell suggested the method now [be]ing adopted that the thing was again taken up. They [ha]d since found that the method was in use in the East of [F]rance, but when it was adopted by them this fact was [no]t known, and it was to them an entirely new invention [b]y Thomas Bell. Mr. Bell then went on to describe the [m]anner of constructing No. 1 bore-hole, and the strata [g]one through. When the salt was found they went [5]0 feet lower, for the sake of experiment, in search [of] coal, but none was found. The Diamond Boring Company did the work. The hole was lined from top to [b]ottom, and the bottom part perforated. A second [t]ube was then inserted. He described how the [fr]esh water was admitted into the hole and the brine [p]umped up. There was no witchcraft about any [p]art of the system; it was as simple a piece of mechanism [as] anybody could desire. A great consideration in the [l]atter was, What would be the effect upon Middlesbrough [if] 10 feet of salt was removed and the upper crust left? [In] the east of France the subsidence occurring was confined to the immediate neighbourhood of the bore-hole. [A]t present they were raising about 320 tons of salt per [w]eek. When the brine was raised it was stored in a [re]servoir, and then put into evaporating pans. For a time [they] had a difficulty in getting the evaporation to go on [sat]isfactorily; but by using Stockton and Middlesbrough [c]oal the difficulty had been overcome. Salt was largely [used] for domestic purposes, and on the Tyne in the manufacture of carbonate of soda. The trade there, however, [wa]s not very brisk, and what the future would bring forward no one could say. Was it not desirable that they [sh]ould be considering whether some new method could not [be] discovered for using the salt? They might adopt the [am]monia process.

THE ENGINEERING TRADE.

THE thirty-second annual report of the Amalgamated Society of Engineers has this week been issued to the members, and the general secretary, Mr. John Burnett, in his introductory remarks, states that the hopeful anticipations of the previous year as to the prospects of trade have been to a great extent realised. It would, perhaps, be too much to say that the general trade of the country, or even of their own trade, had been in a state of unprecedented activity during 1882. There might have been a few years in their trade experience which had been better in point of value of production than last year, but they were few in number. It was, however, almost certain that in no previous year did Great Britain send abroad such a quantity of the various kinds of articles and commodities which they produced for the use of foreign nations. Taking exclusively their own department, they found that the foreign demand for their engines and machinery had increased vastly both in quantity and value. Indeed, it might safely be asserted that never before were the engineers of Britain called upon to produce so much of their work to meet the requirements of foreign customers, and there could be no doubt that so far as their trade was concerned we stood to-day in a better position in the markets of the world than ever we did before. That this had been accomplished in face of the heavy tariffs imposed by foreign nations was a matter of amazement. In most of these countries there seemed to be a tendency to increase rather than decrease their tariffs; but in the United States there seemed to be just now a reaction against protection, and any reduction of their excessive duties could not fail for a time to give a great increase to our American trade. Good as their general trade had been, there could be no doubt that it was in marine engineering they had been most successful. Shipbuilding during 1882 had been carried on to an extent hitherto undreamed of, and the efforts of previous years had been far exceeded. During 1881 the increase of tonnage built by us was something astounding, and reached a total of about 1,000,000 tons. In 1882, however, we far exceeded that great figure, and had constructed 1,200,000 tons of shipping in iron and steel. Under such circumstances as those, their members engaged in the manufacture of marine engines had been well employed, and wages had risen with them to a higher point than before, especially in those places where the organisation of the men was complete. Yet good as this and some other branches of their trade had been, their unemployed list had remained much heavier than in past years of good trade. At the close of 1881 they had 412 branches on their roll. In the course of 1882 they opened new ones at Stockton-on-Tees, Newton Heath, Sunderland, Colchester, Gainsborough, Openshaw, Glasgow, and Woolston at home, and in America at Plainfield, Denver, Taunton, and Erie. Owing to falling off in local trade and removal of members, they had had to close small branches at Inverness, Constantinople, and Port Jervis, and Tredegar from the results of a special audit, leaving them thus to enter 1883 with a total list of 420 branches. Of these they had in England, 302; Scotland, 41; Ireland, 14; Australia, 9; Canada, 0; New Zealand, 4; Queensland, 1; India, 1; United States, 39; Turkey, 1; Malta, 1; and France, 1. This improvement in the number of branches had been due to the increase and spread of trade, and at the close of 1881 they had a grand total of 46,101 members, which they had augmented last year to 48,388, being a gain of 2,287 after allowing for deaths and exclusions. The income of 1882 was not so large as in some previous years, but the amount raised by levying had been remarkably small, the total asked for in this way during the year being only 1s. 3d. per member. Under the head of contributions they had received £115,178, against £124,109 in the previous year; propositions of members had realised £1,214, and entrance fees £3,223, an increase under these two heads of £1,059, and bank interest had amounted to £3,407. Their outlay had fallen considerably as compared with 1881, and was enormously less than in 1879-80. In 1881 they expended £116,621, last year but £102,165, which showed a falling off amounting to £14,458. The greatest saving had taken place under the head of donation benefit, the expenditure in 1882 being only £21,036, as against £38,083 in the previous year. Sick benefit had cost them more than in the previous year, being £25,293, or £663 more than in 1881 and £2,000 more than in 1880. Funerals cost them £218 less than in 1881, being £7,648 against £7,864. The average age of their members at death had also gone up from 45½ years to 45¾ years. Superannuation benefit had again increased, and to such an extent as to eat very materially into their savings, having reached the great total of £28,312, which was an increase of £2,788 on 1881. The peaceful state of their relations with their employers was vouched for by the very trifling sum of £860 spent on contingent benefit, and £35 in grants in defence of their own trade. Benevolent grants had been made in cases of extreme distress to the sum of £1,031, which was almost as low as they could ever expect to have that item of their expenditure. Their general position might be concisely stated as follows:—They had 420 branches, containing an aggregate of 48,388 members. Their total income for 1882 was £124,408 9s. 0½d., and their total expenditure £102,165 7s. 3d., leaving a surplus of income over outlay of £22,243 1s. 9½d., which, added to their last year's balance, gave them an accumulated capital of £168,200 4s. 3d., or £3 9s. 6¼d. per member.

THE APPLICATIONS OF ELECTRICITY.*

THE fourth of the series of six lectures on the applications of electricity was delivered at the Institution of Civil Engineers on April 5, by Dr. J. Hopkinson, F.R.S., M.I.C.E., the subject being "Some Points in Electric Lighting." The following is an abstract of the lecture.

The science of lighting by electricity was divided by the lecturer into two principal parts—the methods of production of electric currents, and of conversion of the energy of these currents into heat at such a temperature as to be given off in radiations to which the eye was sensible. The laws known to connect together those phenomena called electrical were essentially mechanical in form, closely correlated with mechanical laws, and might be most aptly illustrated by mechanical analogues. For example, the terms "potential," "current," and "resistance," had close analogues respectively in "head," "rate of flow," and "co-efficient of friction," in the hydraulic transmission of power. Exactly as in hydraulics head multiplied by velocity of flow was power measured in foot-pounds per second or in horse-power, so potential multiplied by current was power and was measurable in the same units. Again, just as water flowing in a pipe had inertia and required an expenditure of work to set it in motion, and was capable of producing disruptive effects if that motion were too suddenly arrested, so a current of electricity in a wire had inertia: to set it moving electromotive force must work for a finite time, and if arrested suddenly by breaking the circuit the electricity forced its way across the interval as a spark. Corresponding to mass and moments of inertia in mechanics there existed in electricity coefficients of self-induction. There was, however, this difference between the inertia of water in a pipe and the inertia of an electric current—the inertia of the water was confined to the water, whereas the inertia of the electric current resided in the surrounding medium. Hence arose the phenomena of induction of currents upon currents, and of magnets upon moving conductors—phenomena which had no immediate analogues in hydraulics. The laws of induction were then illustrated by means of a mechanical model devised by the late Professor Clerk Maxwell. In the widest sense, the dynamo-electric machine might be defined as an apparatus for converting mechanical energy into the energy of an electro-static charge, or mechanical power into its equivalent electric current through a conductor. Under this definition would be included the electrophorus and all frictional machines; but the term was used in a more restricted sense, for those machines which produced electric currents by the motion of conductors in a magnetic field, or by the motion of a magnetic field in the neighbourhood of a conductor. The laws on which the action of such machines was based had been the subject of a series of discoveries. Oersted discovered that an electric current in a conductor exerted force upon a magnet; Ampère that two conductors conveying currents generally exerted a mechanical force upon each other; Faraday discovered—what Helmholtz and Thomson subsequently proved to be the necessary consequence of the mechanical reactions between conductors conveying currents and magnets—namely, that if a closed conductor moved in a magnetic field, there would be a current induced in that conductor in one direction if the number of lines of magnetic force passed through the conductor was increased by the movement, in the other direction if diminished. Now all dynamo-electric machines were based upon Faraday's discovery. Not only so; but however elaborate it might be desired to make the analysis of the action of a dynamo-machine, Faraday's way of presenting the phenomena of electro-magnetism to the mind was in general the best point of departure. The dynamo-machine, then, essentially consisted of a conductor made to move in a magnetic field. This conductor, with the external circuit, formed a closed circuit in which electric currents were induced as the number of lines of magnetic force passing through the closed circuit varied. Since, then, if the current in a closed circuit was in one direction when the number of lines of force was increasing, and in the opposite direction when they were diminishing, it was clear that the current in each part of such circuit which passed through the magnetic field must be alternating in direction, unless indeed the circuit was such that it was continually cutting more and more lines of force, always in the same direction. Since the current in the wire of the machines was alternating, so also must be the current outside the machine, unless something in the nature of a commutator was employed to reverse the connections of the internal wires in which the current was induced, and of the external circuit. There were then broadly two classes of dynamo-electric machines; the simplest, the alternating-current machine where no commutator was used; and the continuous-current machine, in which a commutator was used to change the connection with the external circuit just at the moment when the direction of the current would change. The theory of the alternate-current machine was then explained, and it was proved that two independently driven alternate-current machines could not be worked in series, but that they might be worked in parallel circuit, and hence were quite suitable for distribution of electricity for lighting without the necessity of providing a separate circuit for each machine.

It was easy to see that, by introducing a commutator revolving with the armature, in an alternate-current machine, and so arranged as to reverse the connection between the armature and the external circuit just at the time when the current would reverse, it was possible to obtain a current constant always in direction; but such a current would be far from constant in intensity, and would certainly not accomplish all the results obtained in modern continuous-current machines. This irregularity might, however, be reduced to any extent by multiplying the wires of the armature, giving each its own connection to the outer circuit, and so placing them that the electromotive force attained a maximum successively in the several coils. A practically uniform electric current was first commercially produced with the ring armature of Pacinotti, as perfected by Gramme. A dynamo-machine was not a perfect instrument for converting mechanical energy into the energy of the electric current. Certain losses inevitably occurred. There was the loss due to friction of bearings, and of the collecting brushes upon the commutator; there was also the loss due to the production of electric currents in the iron of the machine. When these were accounted for, there remained the actual

MOLECULAR MAGNETISM.*

By Prof. D. E. Hughes, F.R.S.

DURING the course of some late researches, which I had the honour to communicate to the Royal Society (p. 57), and experimentally illustrate on the reading of my second paper (p. 105), so many experimental facts occurred, all pointing to the conclusion that ordinary molar magnetism is entirely due to the symmetrical arrangement of its polarised molecules, and that these molecules can be rotated by torsion, so as to decrease its longitudinal magnetism, or increase it if the effect of the elastic torsion is to rotate the molecules in its required longitudinal symmetrical arrangement, and observing that molecular magnetism could induce an electric current upon its own molar constituents, or that an electric current by its passage through an iron wire would produce molecular magnetism, I have continued these researches in the hope of elucidating, as far as possible, the phenomenon of the transformation of electricity and magnetism by the changes produced in the molecular structure of its conducting wire.

For this purpose I have employed three separate methods of investigation, each requiring a slightly modified form of apparatus. The first relates to the influence of an elastic torsion upon a magnetic or conducting wire; the second the influence upon the molecular structure of an iron wire by electricity or magnetism; the third was the evident movement of the molecules themselves as given out in sonorous vibrations. The general details of the apparatus employed having been given (see pp. 57, 81, ante), I will only briefly indicate any modification of the method employed.

1. Influence of an Elastic Torsion upon a Magnetic or an Electric Conducting Wire.

In the paper just referred to I showed that induced currents of electricity would be induced in an iron wire placed on the axis of a coil through which intermittent currents were passing, and that these currents were produced only when the wire was under the influence of a torsion not passing its limit of elasticity. It became evident that if the intermittent magnetism induced by the coil produced under torsion intermittent currents of electricity, that an intermittent torsion under the influence of a constant current of electricity or a constant magnetic field would produce similar currents. This was found to be the case, and as some new phenomena presented themselves indicating clearly the molecular nature of the actions, I will describe a few of them directly relating to the subject of this paper. An iron wire of 20 centims. was placed in the centre or axis of a coil of silk-covered copper wire, the exterior diameter of the coil being 5 centims., having an interior vacant circular space of 3½ centims. The iron wire is fastened to a support at one end, the other, passing through a guide, to keep it parallel but free, so that any required torsion may be given to the wire by means of a connecting arm or index. A sensitive telephone is in direct communication with the coil, or a galvanometer may be used, as the currents obtained by a slow elastic torsion are so that in slow and strong enough to be seen on a very ordinary galvanometer. I prefer, however, the telephone, because it has the inestimable advantage in these experiments of giving the exact time of the commencement or finish of an electric current. It has, however, the disadvantage of not indicating the force or direction of the current; but by means of the sonometer the true value and direction of any current is at once given. Again, the telephone is useless for currents of slow interrupted or permanent current is broken up into rapid intermittent currents, and then we are able to perceive feeble constant currents. For this reason a microphonic rheostat is joined to the telephone and coil. The current from a battery of two bichromate cells is sent constantly through the wire if we wish to observe the influence of the torsion of the wire upon the electric current, or a constant field of magnetic energy is given to the wire by either a separate coil or a permanent magnet. The currents obtained in the coil are induced from the change in the molecular magnetism of the wire, but we may equally obtain these currents on the wire itself without any coil by joining the telephone and rheotome direct to the wire; in the latter case it is preferable to join the wire to the primary of a small induction coil, and the telephone and rheotome upon the secondary, as then the rheotome does not interrupt the constant electric current passing through the wire. As the results are identical, I prefer to place the telephone on the coil first named, as the tones are louder and entirely free from errors of experimentation.

If we place a copper wire in the axis of the coil we produce no effect by torsion, either when under the influence of a constant magnetic field or a current passing through it; nor do we perceive any effects if we place an iron wire (2 millims. in diameter), entirely free from magnetism and through which an electric current has never passed. I mention this negative experiment in order to prove that all the effects I shall mention are obtained only through the magnetism of the wire. If now I pass an electric current for an instant through this same wire, its molecules are instantly polarised, and I have never yet been able to restore the wire to its original condition, and the magnetisation induced by the passage of a current is far more powerful and more persistent in soft iron than tempered steel. This may be due, however, to the fact that in tempered or softened steel we find traces only of a current during the rotation by torsion of its molecules some two to three degrees of sonometer, whilst iron gives constantly a current of 70 sonometric degrees.*

In order to obtain these currents we must give a slight torsion of 5° or 10° to and fro between its zero point. We then have a current during the motion of the index to the right, and a contrary current in moving the index to the left. If we use a galvanometer, we must time these movements with the oscillations of the needle; but with the telephone it gives out continuous sounds for either movement, the interruptions being only those caused by the rheotome. The direction of the current has no influence on the result; either positive to the free arm or index or negative gives equal sounds, but at the moment of reversal of the current a peculiar loud click is heard, due to the rapid change or rotation of the polarisation of its molecules, and this peculiarly loud momentary click is heard equally as well in steel as in iron, proving that it is equally polarised by the current, but that its molecular rigidity prevents rotation by torsion. We can imitate in some degree the rigidity of steel by giving the iron wire several permanent twists. The current due to elastic torsion is then reduced from 70° to 40°, due to the mechanical strain of the twists remaining constant; and a weakening of the current is also remarked if with a fresh wire we pass in torsion its limit of elasticity.

If a new soft iron wire of 2 millims. (giving no traces of a current by torsion) has passed through it a momentary current of electricity, and then wire observed free from the current itself, it will be found to be almost as strongly polarised as when the current was constantly on, giving by torsion a constant of 50 sonometric degrees. If, instead of passing a current through this new wire, I magnetise it strongly by a permanent magnet or coil, the longitudinal magnetism gives also 70° of current for the first torsion, but weakens rapidly, so that in a few contrary torsions only traces of a current remain, and we find also its longitudinal magnetism almost entirely dissipated. Thus there is this remarkable difference, and it is that whilst it is almost impossible to free the wire from the influence produced by a current, the longitudinal magnetism yields at once to a few torsions. We may, however, transform the ring or transversal magnetism into longitudinal magnetism by strongly magnetising the wire after a current has passed through it; this has had the effect of rotating the whole of the molecules, and they are all now symmetrical with longitudinal magnetism, then by a few torsions the wire is almost as free as a new wire; and I have found this method more efficacious than heating the wire red hot, or any other method yet tried. If I desire a constant current from longitudinal magnetism, I place at one of the extremities of the wire a large permanent magnet, whose sustaining power is 5 kilometres, and this keeps the wire constantly charged, resembling in some respects the effects of a constant current. The molecular magnetism or the current obtained by torsion is not so powerful from this, my strongest magnet, as that produced by the simple passage of a current, being only 50 sonometric degrees in place of 70° for that due to the passage of a current. The mere twisting of a longitudinal magnet, without regard to the rotation of its molecule having no effect, is proved by giving torsion to a steel wire strongly magnetised, when only traces of a current will be seen, perhaps one or two degrees, and a constant source of magnetism or electricity then giving no measurable effect. Evidently we have equally twisted the magnetised steel as the soft iron. In the steel we have a powerful magnet, in the soft iron a very feeble one; still the molecular rotation in iron produces powerful currents to the almost absolute zero of tempered steel.*

If we magnetise the wire whilst the current is passing, and keep the wire constantly charged with both magnetism and electricity, the currents are at once diminished from 70° to 30°. We have born two distinct magnetic polarisations at right angles to each other, and no matter what pole of the magnet or of the current the effect is greatly diminished; the rotation of the two polarities would now require a far greater arc than previously. The importance of this experiment cannot as yet be appreciated until we learn of the great molecular change which has really occurred, and which we observe here by simply diminished effects.

If we heat the wire with a spirit flame, we find the sounds increase rapidly from 70 to 90, being the maximum slightly below red heat. I have already remarked in my previous paper this increased molecular activity due to heat, and its effects will be more clearly demonstrated when we deal with the sounds produced by intermittent currents.

Another method, by means of which I have again received proofs of the rotation of the polarised molecule, is to pass an intermittent current through a soft 0·5 millim. iron wire, listening to the results by the telephone joined direct and alone to the coil. If, then, the wire is entirely free from strain, we have silence, but a torsion of 20° produces some 50 sonometric degrees of electric force. If, now (the wire being at zero strain), I bring one pole of the permanent magnet I have already described near the side of the wire, the sounds increase from zero up to 50°, being at their maximum when this magnet is 5 centims. distant; but if we continue to approach the magnet the sounds gradually weaken to an almost zero. The explanation of this fact can be found when we know that the greatest inductive effect on the wire would be when a magnet is at an angle of 45° with the wire. And, also, considering each molecule as a separate independent magnet, we find that at a given distance for a given magnet the force of rotation is equal to that of 45°; by approaching the magnet we increase the rotation but diminish the angular polarity in relation to the wire, hence the decrease of force by the near approach of the magnet. And to prove that the function of the elastic torsion is simply to rotate the polarised molecules similarly to the magnet, we place the wire under an elastic torsion of 20°, and approach gradually the magnet as before. One pole now will be found to increase the sounds or its angular polarity, the other will decrease until at 5 centims. distance as before we have perfect silence; the torsion exists as before, but the molecules are no longer at the same angle. On removing the magnet we find that instead of the usual 50 of current we obtain barely 5 or 10; have we then destroyed the polarity of the molecules, or do they find a certain resistance to their free rotation to their usual place? To solve this question we have only to shake or give the wire a slight mechanical vibration, and then instantly the molecules rotate more freely, and we at once find our original current of 50°. I will forbear mentioning many other experimental proofs of my views by this method, as there are many to relate by different methods in the following chapters.

MOLECULAR MAGNETISM.*

By Prof. D. E. Hughes, F.R.S.

(Concluded from page 276.)

2. Influence upon the Molecular Structure of an Iron or Steel Wire by Electricity or Magnetism.

BEING desirous to modify the apparatus already described, so that it would only give indications of a current if they were of a spiral nature, the wire was kept rigidly at its zero of strain or torsion, and the coil was made so that it could revolve on an axis perpendicular to the wire; by this means, if the wire was free from strain, the centre or axis of the coil would coincide with that of the wire. Thus with a straight copper wire, we should have a complete zero, but if this wire formed a right or left-handed helix, the coil would require moving through a given degree (on an arbitrary scale) corresponding to the diameter and closeness of the spirals in the helix; the degrees through which the coil moved, were calibrated in reference to known copper helices. 50° equalled a copper wire 1 millim. diameter, formed into a helix of 1 centim. diameter, whose spiral turns were separated 1 centim. apart.

In order to obtain a perfect zero and wide readings, with small angular movement of the coil, it is necessary that the return wire should be of copper, 2 millims. diameter, offering comparatively little resistance, and that it should be perfectly parallel with the steel or iron wire. In order that it may react upon the exterior of the coil, it is fastened to the board, so that it is near (1 centim.) the exterior of the coil, and parallel to the iron wire, at a distance of 4 centims. If we consider this return wire alone, we find, as in the sonometer, that if the wire is perpendicular to the exterior wires of the coil, we have a zero or silence, but moved through any degree, we have a current proportionable to that degree; by this means we have an independent constant acting on the coil, constantly aiding the coil in finding its true zero, and allowing of very wide readings, with a comparatively small angular movement of the coil.

The rheotome is joined to a battery of two bichromate cells, and by means of a reversing switch an intermittent current of either direction can be sent through the wire. The telephone is joined direct and alone to the coil, thus no currents react upon the coil when perpendicular to the iron, and its return wire, if not of a spiral nature.

Placing an iron wire 0·5 diameter, and passing a current through it, I found a change had taken place similar to those indicated in my second paper (p. 106), but it was so difficult to keep the wire free from magnetism and slight molecular strains, that I preferred and used only in the following experiments tempered steel wire (knitting needles I found most useful). All the effects are greatly augmented by the use of iron wire, but its molecular elasticity is so great that we cannot preserve the same zero of reading for a few seconds together, whilst with steel, 0·5 millim. diameter, the effects remained a constant until we removed the cause.

I have not as yet been able to obtain a steel wire entirely free from magnetism, and as magnetism in steel has a remarkable power over the direction of the spiral currents, I will first consider those in which I found only traces. On passing the intermittent current through these, the sounds were excessively feeble for either polarity of current, but at each reversal a single loud click could be heard, showing the instant reversal of the molecular polarity. The degree of coil indicating the twist or spirality of the current was 5° on each side of its true zero. The wire was now carefully magnetised, giving 10° on each side for different currents. The positive entering at north pole indicating 10° right-handed spiral, negative entering the same pole, a left-handed spiral, we here see in another form, a fact well known and demonstrated by De la Rive by a different method, that an electric current travels in spirals around a longitudinal magnet, and that the direction of this spiral is entirely due to which pole of an electric current enters the north or south pole. I propose soon, however, to show that under certain conditions these effects are entirely reversed.

If through this magnetised wire I pass a constant current of two bichromate cells, and at the same time an intermittent one, the spiral is increased to 15°, but the direction of the intermittent current entirely depends on that of the constant current; thus, if the positive of the constant current enters the north pole, the intermittent positive slightly increases the spiral to 17°, and the negative to 13°, both being right-handed; the two zeros of the constant battery are, however, as we might expect from the preceding experiment, on equal opposite sides of the true zero; but if we magnetise the wire whilst a constant current is passing through it, a very great molecular disturbance takes place; loud sounds are heard in the telephone, and it requires for each current a movement of the coil of 40°, or a total for the two currents of 80°. This, however, is not the only change that has taken place, as we now find that both constant currents have a right-handed spiral; the positive under which it was magnetised a right-handed spiral of 65°; the negative, a right-handed spiral of 15°, and the true central or zero point of the two currents indicates a permanent spiral of 55°.

This wire was magnetised in the usual way, by drawing the north pole of my magnet from the centre to one extremity, the south from the centre to the other, and this repeated until its maximum effects were obtained; in this state I found, sliding the coil to different portions, that the spiral currents were equal, and in the same direction throughout.

It now occurred to me to try the effect of using a single pole of the magnet; this was done whilst a constant current was passing through the wire, commencing at the extremity, where the positive joined, drawing the north pole through the length of the wire, from positive towards the negative; the effect was most remarkable, as the steel wire now gave out as loud tones as a piece of iron, and the degree on the coil showed 200°. The constant and intermittent currents now showed for either polarity a remarkably strong right-handed twist; the positive 200 right, and the negative 150 right-handed spirals; the molecular strain on its wire from the reaction of the electric current upon the molecular magnetism was so great, that no perfect zero could be obtained at any point, a fact already observed when a wire was under an intense strain, producing tertiary currents that superposed themselves upon the secondary. In order to compare these spiral currents with those obtained from a known helix, I found that taking a copper wire of similar diameter (0·5 millim.), and winding it closely upon the steel wire ten turns to each centimètre, having a total of 200 turns, with an exterior diameter of 1·5 millims., withdrawing the steel wire, leaving this closely wound helix free, that it gave some 190°, instead of the 200 of the steel wire alone; thus the spiral currents fully equalled a closely wound copper wire helix of 200 turns in a similar length.

If it were possible to twist a magnetised wire several turns to the right, and that its line of magnetism would coincide with that of the twist, then on passing a positive or negative current, there would be an apparent augmented or diminished spirality of the current, but both would have a right-handed twist. The result would be identical with the phenomenon described, although the cause is different.

The explanation of this phenomenon can probably be found in the fact that the constant spirality now observed is that of the electric current under which it was magnetised, for whilst magnetising it we had a powerful source of magnetism constantly reacting upon the electric current, and the constant spirality now observed is the result or remains of a violent molecular reaction at the instant of magnetisation, and the remaining evident path or spiral is that of the electric current. On testing this wire as to its longitudinal magnetic force, I found that it was less than a wire simply magnetised in the usual way; thus the effects are internal, affecting the passage of the electric current, giving, however, no external indications (except apparent weakness) of the enormous disturbance which has taken place.

If, instead of drawing the north pole of the magnet as above, from positive towards negative, I draw it from negative to positive, all the effects are repeated, except we have now, as we should expect, a left-handed spiral, but if I draw the magnet from the extremities of the wire to the centre, then at this centre I find an absolute zero of twist, but on each side a contrary twist, the wire then having a left and right-handed twist, the positive travelling towards the centre in a right-handed twist gradually ceasing in zero; this is as we might expect, but if done under the influence of a constant current, no matter what pole of the battery enters afterwards the north pole of the magnet, it will have during its first half a right-handed, and in its second a left-handed spiral. It became important to know if a wire, which had been magnetised under the influence of a current, could be restored to something like its original condition. Electric currents had no effect. Heat, which would not destroy its temper, had no effect. Mechanical vibrations and torsions failed to disturb the molecular arrangement; but by magnetising it strongly by a magnet, when no current was passing, at once brought the wire to its usual apparently rigid state, and the constant or intermittent currents now indicated only 18° of spiral currents against a previous 200°, and the sounds were, as usual, from steel, excessively weak. I have since used this method with invariable success, when I wished to preserve or repeat the experiments upon the same wire. If these experiments are repeated on an iron wire, the effects are far greater in the first instance, so great that they were thrown out of the range of my measurements; it was only after a few seconds of successive reversals that the zero of the wire was brought within range, and although there rapidly decreased, exactly similar effects were observed as in the steel, and as with all moderate ranges, I could bring the iron at once to a complete zero by torsion, and as torsion alone would produce this complete zero, I believe we have here effects from identical causes to those related in the first chapter.

Having noticed in my previous papers the increased molecular activity caused by the approach of a powerful permanent magnet, and believing that the permanent spirality above mentioned was due to this alone, and not to an increased polarity, I magnetised strongly an iron wire giving, as usual, a reversed spiral for different currents of but 10°. I now heated the wire by a spirit-flame to a dull-red heat, whilst the current was passing through it, and on cooling I found a similar but stronger permanent torsion of 250°; both currents, as in the previous experiments, have a right-handed spiral. Thus, a current of electricity passing through a wire, nearly red hot, determines molecular arrangement, or path, which, on cooling, forces currents of either direction to follow the path which had been determined under the influence of heat.

3. Molecular Sounds.

The passage of an intermittent current through iron or other wire gives rise to sounds of a very peculiar and characteristic nature. Page, in 1837, first noticed these sounds on the magnetisation of wires in a coil. De la Rive published a chapter in his "Treatise on Electricity" (1853) on this subject, and he proved that not only were sounds produced by the magnetisation of an iron wire in an inducing coil, but that sounds were equally obtained by the passage direct of the current through the wire. Gassiot, 1844, and Du Moncel, 1878-81, all have maintained the molecular character of these sounds. Reis made use of them in his, the first electric telephone invented, and these sounds have been, since the appearance of Bell's telephone, often brought forward as embodying a new form of telephone. These sounds, however, for a feeble source of electricity, are far too weak for any applied purposes, but they are most useful and interesting where we wish to observe the molecular action which takes place in a conducting wire. I have thus made use of these sounds as an independent method of research, and by their means verify any point left doubtful by other methods, some of which I have already described.

The apparatus was the same as in the last chapter, except that no telephone was used. The intermittent electric current was connected by means of switch key, either with the coil inducing longitudinal magnetism in the wire, or could be thrown instantly through the wire itself, thus rapid observations could be made of any difference of tone or force by these two methods; a reversing key also allowed when desired a constant current of either polarity to pass through the wire under observation.

Iron of all metals that I have yet tried gave by far the loudest tones, though by means of the microphone I have been able to hear them in all metals; but iron requires no microphone to make its sounds audible, for I demonstrated at the reading of my paper, March 31st, that those sounds with two bichromate cells were clearly audible at a distance. A fine soft iron wire (No. 28) is best for loud sounds to be obtained by the direct passage of the current, but large wires (1 millim.) are required for equally loud tones from the inducing coil. By choosing any suitable wire between these sizes we can obtain equal sounds from the longitudinal magnetism or direct current. The wire requires to be well annealed; in fact, as to all preceding experiments, the sounds are fully doubled by heating the wire to nearly red heat. There are many interesting questions that these molecular sounds can aid in resolving, but as I wish to confine the experiments to the subject of the two preceding chapters, I will relate only a few which I believe bear on the subject.

On sending an intermittent electric current through a fine soft iron wire we hear a peculiar musical ring, the cadence of which is due to that of the rheotome, but whose musical note or pitch is independent both of the diameter of the wire and the note which would be given by a mechanical vibration of the wire itself. I have not yet found

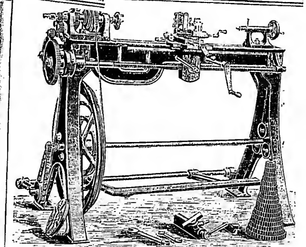
THE NATURE OF ELECTRICITY.

IN two lectures recently delivered before the Royal Institution, Prof. O. J. Lodge, F.R.S., endeavoured to explain to crowded audiences the modern views of the real nature of electricity. It was often said, he remarked, that we did not know what electricity was, and the statement was still largely true, but it was not so true as it was twenty years ago. Some things were beginning to be known about it, and though modern view were tentative, and might well require modification, nevertheless, some progress had been made, and it was not unsuitable at the beginning of a new year of progress and discovery to try and set forth the position of thinkers on electrical subjects at the present time. It had been discovered by Faraday and by Clerk-Maxwell how like the behaviour of electricity was to that of an incompressible fluid or liquid. One was not thereupon justified in asserting that electricity was a liquid, but it was perfectly certain that it behaved in many respects exactly like one, and it was, therefore, a step necessary to be made to understand and grasp the analogy between electricity and a liquid—in other words, to develop a liquid theory of electricity. Let them imagine a fish in the deep sea; he was surrounded and permeated by water, but must be completely unconscious of its existence. For a fish near the surface even to postulate the existence of water from the effects of currents and waves would be an act of scientific discovery analogous to our discovery of the existence of the atmosphere; but for a fish in the serene depths of the ocean the discovery of water would be an almost impossible one. Now, we were living immersed in electricity in precisely the same way, but we were in a more favourable position for discovering its existence, because it behaved for the most part more like a liquid entangled in some elastic medium or jelly than like a freely moving liquid. Substances in which it could freely move about were called conductors, substances in which it was entangled were insulators or dielectrics. Conductors must be regarded as holes and tubes in the jelly, permitting storage and transfer. The jelly was such as only to resist the motion of electricity; it permitted the free locomotion of ordinary matter. The existence of these two classes of bodies, conductors, and insulators, had enabled the human race with difficulty at length to discover the existence of this all-permeating liquid. An electrical machine was to be regarded as a pump which could transfer the fluid from one cavity to another; thus charging one conductor negatively, the other positively. Charge was to be regarded as either excess or defect from the normal supply of fluid, causing a strain. Electrical attraction and repulsion were all explicable by the strains thus set up in the surrounding elastic medium or jelly. The increase of the capacity of a conductor by bringing an earth-connected body near it was accurately representable by thinning the elastic coat surrounding a cavity, and a hydrostatic model of a Leyden jar could be easily made with an elastic bag inside a rigid vessel, with pressure gauges for electrometers; this behaved in all respects exactly as a Leyden jar—exhibiting discharge by alternate contacts and everything. Discharge was typified by a relaxing of the strain and by twisting of the dielectric medium in some place. Certain phenomena connected with discharge suggested obscurely that what we called negative charge was not merely a defect of supply, but was a supply of a something of an opposite kind—that there were, in fact, two electricities, positive and negative, which combined together into a neutral liquid. It might be that the ether was then composed, and that what we called an electric current was really the simultaneous transfer of the true components of this liquid in opposite directions, and that strains in dielectrics were due to attempted shear of the other. The phenomena of electrolysis strongly suggested and supported this view. Was any other motion possible to a liquid? Yes, a whirling and vibrating motion. By coiling up a conductor so as to get an electrical whirl, we discovered that we had produced a magnet, and all the phenomena of magnetism could be developed on the hypothesis that magnets consisted of such electrical whirlpools. One whirl had the power of exciting another in neighbouring conductors, and these so excited whirls were repelled. In this way could be explained the phenomena of diamagnetism. A disc of copper at the end of a torsion arm was repelled by a magnet until the current induced in it had died away, which was very soon in that particular case; but currents in molecules might, for all we know, last for ever until actively destroyed. Atoms were already endowed with perfect elasticity—why not with perfect conductivity too? Finally, electricity in vibration, if rapid enough, constituted light; and it was easy to see that on this hypothesis conductors must be opaque, and that transparent bodies must insulate, which agreed with observation. If a ray of light were passed along a line of magnetic force, it ought to be twisted, as was shown by the pertinacious experimental power of Faraday before the fact could be understood and before the scientific world was ready to receive it. The profound significance of this fact was first perceived by Sir William Thomson, and stated by him in a most powerful and remarkable note, and upon this Maxwell founded his electrical theory of light. "I have endeavoured," added the lecturer, "to give you pictorial and mechanical representations of electrical phenomena, and thus to lead you a step in the direction of the truth; but I must beg you to remember, that it is only a step, and that what modifications and addenda will have to be made to the views here explained I am wholly unable to tell you."

53



THE BRITANNIA COMPANY'S SCREW-CUTTING LATHES.

ON page 104, Vol. XXXIII., we illustrated and described a new self-acting screw-cutting lathe, brought out by the Britannia Company, as a serviceable machine at a low price. At that time there was nothing like it in the market, and so much success has followed its introduction, that the company now make larger lathes of the same design, which have received the attention of the Government in the shape of orders, the best of testimonials. The illustration in Vol. XXXIII. represented lathe No. 13. The present engraving serves for either No. 15 or No. 16, the difference being only in dimensions and weight. Supposing it to represent No. 15, it is a self-acting, sliding, and screw-cutting lathe, with a 4ft. gap-bed, and centres of 4, 4½, and 5in., as may be desired, at a small difference in cost. The cast-steel mandrel has conical necks running in gun-metal collars; the cone pulley has three speeds for gut band, and is fitted with reversing motion for cutting right or left-hand screws. The compound slide-rest has long bearings, the top slide swivelling to 50° each side of centre. The bed is 6½in. wide, and 4½in. deep, with a gap of 4½in. The lead screw is 1¼in. diameter, and ½in. pitch, and the gun-metal nut is in halves, so as to be readily detached. There is a rack and pinion for quick return. A full set of twenty-two change-wheels, to cut from one to sixty threads per inch, is supplied, and the lathe can be fitted with overhead motion for a comparatively small extra charge. The No. 15 lathe measures 2ft. 6in. between centres, swings 1ft. 4in. in gap, and 8in. over bed; but, as mentioned above, it can be had with 5in. centres. The No. 16 lathe is similar in design and fitting, but is much heavier. It is nominally a 5in. lathe, with a 5ft. gap-bed, the gap being 5½in. deep, by 6¼in. wide, but it can be had, at a small extra cost, with 6ft. bed, 6in. centres, and with flat pulleys for belts. The Company make larger lathes, but Nos. 13, 15, 16 are especially adapted for the amateur's workshop, and for any purpose to which a foot-lathe is applicable. They, in fact, supply a want—a cheap sliding and screw-cutting lathe.

THE AGE OF ELECTRICITY.*

By Prof. S. P. Thompson.

IT is the fashion amongst ethnologists to classify the successive stages of development in the primitive races of mankind by reference to the kind of implement which marked the degree of civilisation to which they had attained. A chipped flint arrow, a bronze spear-head, an iron dagger are typical of the several grades of advancement in material civilisation which we familiarly name the age of stone, the age of bronze, the age of iron. To these three primitive ages you must allow me to add three others, equally well defined—the age of gunpowder, the age of coal and steam, and the age of electricity. The world is even now entering upon a new, and I am fain to believe a happier, age, wherein, whilst delivered to a large degree from the darker aspects, we shall enjoy to a degree hitherto unknown the advantages of machine-aided production. Our machinery will be driven, not by steam, but by electricity; for electricity will be our servant to do the hard work of the world in the coming age. For a quarter of a century we have harnessed that messenger, more nimble than fleet-footed Iris, to convey our thoughts. We have but lately discovered that electricity could also convey the actual tones of our speech. It is electricity that rings our bells, that silvers our pewter and gilds our pinchbeck, that fires our torpedoes, and brings Greenwich time to our clocks. True, these are light and easy duties, but it has taken us many years to adopt in practical life these simplest applications. And, mark you, the delay is not to be imputed to science, for science has known most of these things for forty years. Mines were fired by electricity in 1749; electro-plating with silver was discovered in 1805; an electric telegraph was in actual operation in London in 1816; electric bells were invented in 1831; electric clocks were made in 1840; and speech was transmitted by an electric telephone in 1861. But, familiar as are these services to mankind, there are other services of a very important nature which electricity is perfectly competent to perform which, unless the world has grown wiser, will not, I suppose, be generally adopted for the next 10 years. Electricity can bring us a magnificent and economical light. It can smelt our most refractory metals. It can bleach our cottons and print our calicoes. It can detect base coins without cutting them, and can discover a bullet in a wound without probing it. It can stencil our circulars, grind our coffee, gather our apples and walnuts, protect us against burglars, turn our sewing machines, drive our tricycles. Nay, it can perform much heavier work. It can turn lathes, saw timber, grind scissors and knives, plane planks, propel tramcars, and, as I can personally testify, can furnish motive power of a very effective kind to an iron boat. Surely we have reason to say that the age of electricity has already begun. The success of primitive attempts to utilise electricity as a motive power was not very encouraging, for their cost was great and their power weak. The fact was that though the machinery—on a small scale at any rate—was ready, the time was not ripe for it. Compact and light in weight, these little electric motors presented, for light kinds of work, an enormous advantage over steam-engines; yet these advantages were far outweighed by the consideration that the cost of generating electric currents in the voltaic battery

* From a lecture delivered October 7, at the University College, Bristol.

54

nto opponents. If the bill now before the Commons reaches the House of Lords by the middle of July, the fate of the ventilators is sealed. There will, we hear, be a desperate effort to obstruct the measure on the part of the railway interest, however, and it is just possible that its passage may be postponed until next session.

A GREAT WIRE ROPE.

The great driving-rope which is to pull the cars across the new Brooklyn bridge has arrived at New York. The rope is 1½ inch in diameter, 11,700 feet long, and weighs 11 tons. It is accompanied by a duplicate rope of the same weight and strength, which is to be held in reserve for use when the first rope wears out. The test which it has been subjected to gives ample assurance of its strength. Before it left the works, every wire held at least 1,000 lb., and was stretched from 4 to 6 per cent. more. In order to protect it from the atmosphere, and also to supply to the interior a kind of lubricator when it comes to be used, the rope has received a coating of tar. The rope was manufactured by the J. A. Roebling Company's Wire-works, Trenton, New Jersey.

A NEW STEELWORKS.

The North-Eastern Steel Company made their first heat of steel in the Bessemer department on May 31, with highly satisfactory results, the rolling operations, both of blooms and finished rails, being also very successfully conducted at the same time. The works (as we learn from the *North-Eastern Daily Gazette*, from which the following particulars have been taken) are situated in the marshes on land adjoining the North-Eastern Railway Company's marsh sidings at Middlesbrough. They occupy 22 acres of ground, which is in the form of a triangle lying with its base towards the river—the river itself being the north boundary. The general manager (Mr. Cooper) in planning the works has contrived that the basic shop shall be at the northern end of the land, and the Bessemer shop, cogging and rail mills, and finishing shop, shall follow in the order named towards the south. The raw material for the lining of the vessels is taken up an incline and shot into bunkers, from which it is drawn in barrows, and elevated by means of a hydraulic hoist to a height of 34 feet, where it is charged into the basic cupolas, three in number, and there burnt. When sufficiently burnt it is drawn out at the bottom and allowed to cool on the floor, and sorted. It is then loaded into barrows and taken up another hoist, and shot into hoppers over the stone crushers. Passing through the crushers it again falls into hoppers, from which it is supplied by gravitation into several other grinding and mixing machines. By means of this machinery it is mixed with a certain quantity of tar to the consistency of stiff paste. It is then considered in proper form for lining the converters, and for the making of converter plugs. When the converters are lined, fire and coke are put into them until the lining is sufficiently baked. The converter shells, whilst being lined, are ranged under a 30-ton steam travelling crane, having a span of 45 feet, by which means they are readily handled and moved to any desired position. After being lined they are placed upon suitable carriages and taken underneath the converter stage, and are lifted into position either by means of an hydraulic jack-ram or a 60-ton steam travelling crane, as the case may be. The firm propose to work, eventually, on the direct system—that is, taking molten iron from the surrounding furnaces direct to the converter; but at present they are working cold pig only, which is, of course, bought in the Cleveland and surrounding district.

The pig-iron cupolas, three in number, are arranged so that the raw material is taken up to a height of 21 feet by means of a 20-ton hydraulic lift, and there charged with the necessary quantity of coke and limestone. When melted the iron is drawn out on the ground floor into 12-ton ladles, and then pushed forward by means of a small locomotive to another 20-ton lift, by which it is hoisted to the converters' stage level, which is 21 feet above the ground line, also on the same level as the charging stage. It is then pushed forward to the front of the converter by a small locomotive which is in waiting on the converter staging. The ladle is then tipped by means of a worm-and-wheel into a short spout, from which it runs into the converter. The ladle is withdrawn, the blast is put on, the vessel turned up, and the process of blowing begun. After the usual careful tests have been taken, and the steel found to be sufficiently blown, it is poured into a ladle carried by a transfer crane. This crane receives from two converters, another similar crane receives from other two converters, there being four 15-ton converters in the plant. The steel in the ladle is poured into another ladle carried by a centre casting crane, which covers a pit 60 feet in diameter. This crane was specially designed for the plant by Messrs. Head & Wrightson, of Stockton, the type having been patented by Mr. Wrightson. In this pit moulds of any required form are placed, and steel is then drawn off, ingot by ingot, until the ladle is exhausted. The ingot moulds are removed by means of four 6-ton cranes, which are arranged round the pit, and the ingots are placed on bogies and taken to Mr. Gjers' soaking pits. After remaining in these pits about twenty minutes, they are taken out by a hydraulic crane, which lifts them on to the cogging mill rollers. The cogging mill has rolls 36 inches diameter, and 7 feet 6 inches long. The engines for driving this mill have cylinders 40 inches diameter, 5 feet stroke, and geared at 2 to 1. In this mill large slabs 16 inches wide will be made; also rail blooms for export or the English trade. The bloom, or slab, having been brought down to the required size in the mill, is passed forward by means of live-rollers to the bloom shears, where the crop ends are cut off, and the bloom itself cut to any requisite length. The blooms, if required for export, are then placed on a skid and moved along to the outside of the mill, where they are arranged on extensive banks for inspection; but if they are to be still further manipulated, they are run down by means of live-rollers to the roughing mill. The roughing rolls are 28 inches diameter and 7 feet long, and are driven by a pair of engines having cylinders 50 inches diameter and 5 feet stroke, working direct. The bloom here is again passed backwards and forwards until it reaches the desired form. On coming out of the last train it is directed to a train of rollers, which takes it to the billet shears or the rail saw, as the case may be. If billets are being made, after being cut to requisite length they are taken on a skid to the outside of the mill, as in hot banks, and allowed to cool. When sufficiently cooled, they are removed by means of two 3-ton steam portable cranes to the cold banks, thence to the straightening machines and rail drills, and afterwards to the benches, where they are inspected and loaded on trucks, which are placed in docks alongside these benches. The company have commodious sidings connected, of course, with the North-Eastern Railway system. Such is a brief account of the works as they now stand; but the company have in reserve 13 acres of land for further extensions.

THE APPLICATIONS OF ELECTRICITY.*

The last of the series of six lectures on the practical applications of electricity, being on "Electrical Units of Measurement," by Sir William Thomson, F.R.SS.L. and E., M.I.C.E., was delivered on May 3, at the Institution of Civil Engineers. The following is an extract of the lecture:—

The lecturer began by observing that no real advance could be made in any branch of physical science until practical methods for a numerical reckoning of phenomena were established. The "scale of hardness" for stones and metals used by mineralogists and engineers was alluded to as a mere test in order of merit in respect to a little understood quality, regarding which no scientific principle constituting a foundation for definite measurement has been discovered. Indeed, it must be confessed that the science of strength of materials, so all important in engineering, is but little advanced, and the part of it relating to the quality known as hardness least of all. In the last century Cavendish and Coulomb made the first advances towards a system of measurement in electrical science, and rapid progress towards a complete foundation of the system was effected by Ampère, Poisson, Green, Gauss, and others. As late as ten years ago, however, regular and systematic measurement in electrical science was almost unknown in the chief physical laboratories of the world; although as early as 1858 a practical beginning of systematic measurement had been introduced in the testing of submarine telegraph cables. A few years have sufficed to change all this, and at this time electric measurements are of daily occurrence, not in our scientific laboratories only, but also in our workshops and factories where is carried on the manufacture of electric and telegraphic apparatus. Thus, ohms, volts, ampères, coulombs, and micro-farads are now common terms, and measurements in these units are commonly practised to within 1 per cent. of accuracy. It seems, indeed, as if the commercial requirements of the application of electricity to lighting and other uses of every-day life were destined to influence the higher region of scientific investigation with a second impulse, not less important than that given thirty years ago by the requirements of submarine telegraphy. A first step toward the numerical reckoning of properties of matter, is the discovery of a continuously-varying action of some kind, and the means of observing and measuring it in terms of some arbitrary unit or scale division; while the second step is necessarily that of fixing on something absolutely definite as the unit of reckoning.

A short historical sketch was given of the development of scientific measurement, as applied to electricity and magnetism, from its beginning with Cavendish, about 100 years ago, to the adoption of the absolute system of measurement by this country in 1868, at the instance of the British Association Committee on Electric Standards. The importance in the development of the originating work of Gauss and Weber was pointed out, as also of the eight years' labours of the British Association committee. This committee not only fairly launched the absolute system for general use, but also effected arrangements for the supply of standards for resistance coils, in terms of a unit, to be as nearly as possible 10^9 centimetres per second. This unit afterwards received the name of the ohm, which was adopted from a highly suggestive paper which had been communicated to the British Association in 1861 by Mr. Latimer Clark and Sir Charles Bright, in which some very valuable scientific methods and principles of electric measurement were given, and a system of nomenclature—ohmas, kilohms, farads, kilofarads, volts, kilovolts—now universally adopted with only unessential modification, was proposed for a complete system of inter-dependent electric units of measurement. At the International Conference for the Determination of Electrical Units, held at Paris in 1882, the absolute system was accepted by France, Germany, and the other European countries; and Clark and Bright's nomenclature was adopted in principle and extended. Gauss' principle of absolute measurement for magnetism and electricity is merely an extension of the astronomer's method of reckoning mass in terms of what may be called the universal gravitation unit of matter, and the reckoning of force, according to which the unit of force is that force which, acting on unit of mass for unit of time, generates a velocity equal to the unit of velocity. The universal gravitation unit of mass is such a quantity of matter, that if two quantities, each equal to it, be placed at unit distance apart, the force between them is unity. Here mass is defined in terms of force and space, and in the preceding definition force was defined in terms of mass, space, and time. Eliminating mass between the two, it will be found that any given force is numerically equal to the fourth power of the velocity with which any mass whatever must revolve round an equal mass, fixed at such a

55

hand to gain their confidence, and they easily learn to come to take it without fear. The young chicks are given a few earth-worms to counteract any tendency to constipation when first put upon the dry, fine food, and that is the only medicine they ever get or require.

We have heretofore had to contend with all the ills to which chickens are supposed to be heirs, and have used innumerable nostrums, scarcely ever raising a brood free from ailments. But for the last two years no lice, no gapes, no influenzas, no deformities or weaknesses have invaded our precincts. Our eggs are large, rich and fertile, scarcely any failing to hatch; our chicks are healthy, vigorous, independent, and rapid growers. The old fowls are now beginning to moult. We sold once nine dozen eggs per hen in the first six months of the year, besides all we used in the family, and that is the primary object of keeping the fowls.

THREE USEFUL HINTS.

The nuts on hand-hole plates at the rear end of a horizontal tubular boiler, being exposed to considerable heat, are very apt to stick. The most common way of removing them is to use a hammer and chisel, which either breaks the bolt or takes the corners off the nuts. My plan (writes a correspondent of the *American Machinist*) is, at night to saturate a piece of cotton waste with kerosene oil and lay it over the nut till the next morning; then I frequently find I can remove it with my fingers, not requiring even a wrench.

It frequently takes hard hammering to get manhole covers loose. I fill the annular space around the outside with kerosene, and the next morning find the rubber and scale entirely loose, and can remove the cover without trouble.

To cut a water-line glass to right length, I wind a fine cord each side of where I want to break it, leaving room between the two cords for a thicker cord; then put cloth around the glass and hold it in the vice, pass the thick cord (about 3ft. long) once round the glass between the two cords, pull it back and forth till it burns, cool the hot place in the glass with water, and it will break square across. This is much better than using a file, as then you are never sure where the glass will break.

Hudson's Bay as a Grain Route.—The Newfoundland sealing steamship *Neptune*—the same which two years ago was sent in search of Lieut. Greely—sailed from Halifax, N.S., July 22, in command of Lieut. A. R. Gordon, of the Canadian meteorological service, for the purpose of establishing stations for scientific observations in Hudson's Bay. The stations are to be located six on the strait and one on the west shore of the bay. At all the stations the usual meteorological observations will be made; heavy tides will be measured; the drift of water will be noticed, and the conditions and state of the ice. Each station party will consist two men and an Esquimau interpreter, besides the officer in charge, and sufficient provisions and fuel for fifteen months will be supplied. The observatories are made in sections, and will be taken out by the steamer, and put up on the sites selected by the commander as the vessel progresses through the strait. Next year these stations will be revisited, and other parties left in charge. The most important work the parties will be called upon to perform will be to carefully watch and note the breaking up of the ice, the tides, and all other characteristics pertinent to navigation. The sum of 70,000 dols. has been appropriated by the Canadian Government to make these explorations; but the immediate end in view is practical rather than scientific. It is thought that, notwithstanding all the unfavourable reports so far received, it may be found that Hudson Strait is open a sufficiently long period in the late summer and early fall of each year to make it profitable to ship grain by that way to Liverpool from the Winnipeg Valley, which is directly connected with the western shore of Hudson's Bay by the Nelson and Churchill rivers. Lieut. Gorringe investigated this question about three years ago, on behalf of the Northern Pacific Railroad Company, but he reported that any successful trade in this way was impracticable, on account of the fogs as well of the ice, which would hardly leave an average period of six weeks for tolerably safe navigation, while even this period varied with the season, and during such time navigation was often interrupted. The Manitobans are not yet convinced, however, and the recent rapid growth of that province has induced the Dominion government to send out this expedition to make a more thorough investigation.

It has been found that a mixture of seventy parts of air and thirty parts of hydrogen gas ignites at a temperature between 1,026° and 1,028° Fah., while the ignition point of a mixture of coal gas with air in similar proportions varies from 1,202° to 1,216°.

BRITISH ASSOCIATION.

PRESIDENT'S ADDRESS.

THE fifty-fourth annual meeting of the British Association for the Advancement of Science, was opened at Montreal on Wednesday last, the 27th inst., by Lord Rayleigh, M.A., F.R.S., Professor of Experimental Physics in the University of Cambridge, with the following address:—

It is no ordinary meeting of the British Association which I have now the honour of addressing. For more than fifty years the Association has held its autumn gathering in various towns of the United Kingdom, and within those limits there is, I suppose, no place of importance which we have not visited. And now, not satisfied with past successes, we are seeking new worlds to conquer. When it was first proposed to visit Canada, there were some who viewed the project with hesitation. For my own part, I never quite understood the ground of their apprehension. Perhaps they feared the thin edge of the wedge. When once the principle was admitted, there was no knowing to what it might lead. So rapid is the development of the British Empire, that the time might come when a visit to such out-of-the-way places as London or Manchester could no longer be claimed as a right, but only asked for as a concession to the susceptibilities of the English. But, seriously, whatever objections may have at first been felt soon were outweighed by the consideration of the magnificent opportunities which your hospitality affords of extending the sphere of our influence and of becoming acquainted with a part of the Queen's dominion which, associated with splendid memories of the past, is advancing daily by leaps and bounds to a position of importance such as not long ago was scarcely dreamed of. For myself, I am not a stranger to your shores. I remember well the impression made upon me, seventeen years ago, by the wild rapids of the St. Lawrence, and the gloomy grandeur of the Saguenay. If anything impressed me more, it was the kindness with which I was received by yourselves, and which I doubt not will be again extended, not merely to myself, but to all the English members of the Association. I am confident that those who have made up their minds to cross the ocean will not repent their decision, and that, apart altogether from scientific interests, great advantage may be expected from this visit. We Englishmen ought to know more than we do of matters relating to the Colonies, and anything which tends to bring the various parts of the Empire into closer contact can hardly be overvalued. It is pleasant to think that this Association is the means of furthering an object which should be dear to the hearts of all of us; and I venture to say that a large proportion of the visitors to this country will be astonished by what they see, and will carry home an impression which time will not readily efface.

To be connected with this meeting is, to me, a great honour, but also a great responsibility. In one respect, especially, I feel that the Association might have done well to choose another President. My own tastes have led me to study mathematics and physics rather than geology and biology, to which naturally more attention turns in a new country, presenting as it does a fresh field for investigation. A chronicle of achievements in these departments by workers from among yourselves would have been suitable to the occasion, but could not come from me. If you would have preferred a different subject for this address, I hope, at least, that you will not hold me entirely responsible.

At annual gatherings like ours, the pleasure with which friends meet friends again is sadly marred by the absence of those who can never more take their part in our proceedings. Last year my predecessor in this office had to lament the untimely loss of Spottiswoode and Henry Smith, dear friends of many of us, and prominent members of our Association. And now, again, a well-known form is missing. For many years Sir W. Siemens has been a regular attendant at our meetings, and to few indeed have they been more indebted for success. Whatever the occasion, in his Presidential Address of two years ago, or in communications to the Physical and Mechanical Sections, he had always new and interesting ideas, put forward in language which a child could understand, so great a master was he of the art of lucid statement in his adopted tongue. Practice with Science was his motto. Deeply engaged in industry, and conversant, all his life, with engineering operations, his opinion was never that of a mere theorist. On the other hand, he abhorred rule of thumb, striving always to master the scientific principles which underlie rational design and invention.

The Conditions of Successful Invention.

It is not necessary that I should review in detail the work of Siemens. The part which he took, during recent years, in the development of the dynamo-machine must be known to many of you. We owe to him the practical adoption of the method, first suggested by Wheatstone, of throwing into a shunt the coils of the field-magnets, by which a greatly improved steadiness of action is obtained. The same characteristics are observable throughout—a definite object in view and a well-directed perseverance in overcoming the difficulties by which the path is usually obstructed.

These are, indeed, the conditions of successful invention. The world knows little of such things, and regards the new machine or the new method as the immediate outcome of a happy idea. Probably, if the truth were known, we should see that, in nine cases out of ten, success depends as much upon good judgment and perseverance as upon fertility of imagination. The labours of our great inventors are not unappreciated, but I doubt whether we adequately realise the enormous obligations under which we lie. It is no exaggeration to say that the life of such a man as Siemens is spent in the public service; the advantages which he reaps for himself being as nothing in comparison with those which he confers upon the community at large.

As an example of this it will be sufficient to mention one of the most valuable achievements of his active life—his introduction, in conjunction with his brother, of the regenerative gas furnace, by which an immense economy of fuel (estimated at millions of tons annually) has been effected in the manufacture of steel and glass. The nature of this economy is easily explained. Whatever may be the work to be done by the burning of fuel, a certain *temperature* is necessary. For example, no amount of heat in the form of boiling water, would be of any avail for the fusion of steel. When the products of combustion are cooled down to the point in question, the heat which they still contain is useless as regards the purpose in view. The importance of this consideration depends entirely upon the working temperature. If the object be the evaporation of water or the warming of a house, almost all the heat may be extracted from the fuel without special arrangements. But it is otherwise when the temperature required is not much below that of combustion itself, for then the escaping gases carry away with them the larger part of the whole heat developed. It was to meet this difficulty that the regenerative furnace was devised. The products of combustion, before dismissal into the chimney, are caused to pass through piles of loosely-stacked firebrick, to which they give up their heat. After a time the firebrick, upon which the gases first impinge, becomes nearly as hot as the furnace itself. By suitable valves the burnt gases are then diverted through another stack of brickwork, which they heat up in like manner, while the heat stored up in the first stack is utilised to warm the unburnt gas and air on their way to the furnace. In this way almost all the heat developed at a high temperature during the combustion is made available for the work in hand.

The Study of Physics.

As it is now several years since your presidential chair has been occupied by a professed physicist, it may naturally be expected that I should attempt some record of recent progress in that branch of science, if indeed such a term be applicable. For it is one of the difficulties of the task that subjects as distinct as mechanics, electricity, heat, optics and acoustics, to say nothing of astronomy and meteorology, are included under physics. Any one of these may well occupy the life-long attention of a man of science, and to be thoroughly conversant with all of them is more than can be expected of any one individual, and is probably incompatible with the devotion of much time and energy to the actual advancement of knowledge. Not that I would complain of the association sanctioned by common parlance. A sound knowledge of at least the principles of general physics is necessary to the cultivation of any department. The predominance of the sense of sight as the medium of communication with the outer world, brings with it dependence upon the science of optics; and there is hardly a branch of science in which the effects of *temperature* have not (often without much success) to be reckoned with. Besides, the neglected borderland between two branches of knowledge is often that which best repays cultivation, or, to use a metaphor of Maxwell's the greatest benefits may be derived from a cross fertilisation of the sciences. The wealth of material is an evil only from the point of view of one of whom too much may be expected. Another difficulty incident to the task, which must be faced but cannot be overcome, is that of estimating rightly the value, and even the correctness, of recent work. It is not always that which seems at first the most important that proves in the end to be so. The history of science teems with examples of discoveries which attracted little notice at the time, but afterwards have taken root downwards and borne much fruit upwards.

The Development of Electricity.

One of the most striking advances of recent years is in the production and application of electricity upon a large scale—a subject to which I have already had occasion to allude in connection with

The Iron Age - Nov. 13, 1886.

Electrical Measurements and Nomenclature.

BY JOHN W. NYSTROM.

The metric system was originated for the purpose of removing the confused systems of weights and measures which existed in France about a century ago. It was intended to make the metric system uniform for all measurements, but it was found to be impracticable for the circle and time, but with these exceptions it is a uniform system for all measurements. By the introduction of the metric system into England for electrical measurements, the British Association for the Advancement of Science undertook to destroy the uniformity of that system by introducing an odd unit of force called *dyne*, which is 0.98 of a milligram. The B. A. has also introduced an odd unit of work called *erg*, and finally an odd unit of power which they call *Watt*. These three units, *dyne*, *erg* and *Watt*, do not agree with the metric nor with any other established system of measurement, and they are therefore an unnecessary confusion.

The English have so many different units of forces that it is unnecessary to increase the confusion with more of them. They have the *avoirdupois*, the *troy*, the *apothecary*, the *carat* and two kinds of tons, &c., and why not have a separate unit of force for steam, a second for water and a third for air, and call these three forces *Tom*, *Dick* and *Harry*, which would not be more ridiculous than to establish odd units and names of force, power and work in electro-dynamics.

The reason given by the English for christening a unit of electric power with the name *Watt* is, they say, that James Watt discovered power, which is a great error. The English, including the B. A., do not know to this day what power is; but they treat it as work done in a unit of time, and the nearest definition they can give of power is that it is the *rate of doing work*. Power and work are two distinct principles, neither one of which can be converted into the other. Had the B. A. defined power to be the product of force and velocity, it would have indicated that they understood the subject; but, although that definition has been before them for some 20 years, they do not seem to be able to take it in.

The small unit of electric power which they propose to call *Watt* is based upon the *dyne* and *erg*, which were established by the B. A. some 60 odd years after the death of James Watt, who had therefore nothing to do with it, and it is therefore unreasonable to call that unit *Watt*. It would be more reasonable to call that unit of power *Thomson* or *Sir William*, because Sir William Thomson is the ostensible father of the units *dyne* and *erg*.

One objection to the name *dyne* is that the English do not know the proper pronunciation of the letter *y*, and, in the languages in which that is known, the word *dyne* will be pronounced with an entirely different sound from that in English. There are no new names nor new units of force, power and work necessary in electro-dynamics, for we have in the metric system all that is required. The milligram should be the unit of electro-motive force, even if it is called *Volt*, but it would be better to call it with its proper name.

The present value of the *Ampère* corresponds with a velocity of current of about 101.5 kilometers per second, which should be increased to 1000 kilometers. This unit should be called *velocity*, instead of Ampère or intensity. The object of increasing the unit Ampère from 101.5 to 1000 kilometers per second is to bring electro-dynamics to the level with ordinary mechanics, which would make the subject easily understood in conceiving and comparing magnitudes of electrical and mechanical quantities, as will be seen hereafter. The present values of the units Volt and Ampère destroy the uniformity of the metric system in electro-dynamics, while by changing these units as herein proposed, that uniformity would be preserved.

The present galvanometer will be correct for the metric system within 1½ per cent., but one more decimal should be pointed off for the new reading; that is, 15 old Ampères should be noted 1.5 new Ampères, and 8 old Ampères should be 0.8 new Ampères, &c. A force of 1 milligram moving with a velocity of 1000 kilometers per second is equal to a power of 1 kilogram moving 1 meter per second, which unit of power should be called *effect*, and 75 such effects is 1 horse-power.

It may be remarked that this unit of power is too large for small electric currents, which objection can be removed by a smaller unit of power, namely, *milleffect*—that is, one effect is 1000 millefects, or 1 milleffect is a power of lifting 1 gram 1 meter per second, or 1 milligram 1 kilometer per second. A still smaller unit of power may be adopted, namely, *microfect*, which would be the raising of 1 milligram with a velocity of 1 meter per second. The term *effect*, as applied to power, was, I believe, originated by Arthur Morin, at Metz, over 50 years ago, and I learned that term from Morin's Mechanics and at the Royal Technological Institute, Stockholm, and it therefore comes natural to me to call that unit of power *effect*.

The unit of resistance, or Ohm, should be diminished in proportion to the increase of the new unit Ampère, or unit of velocity—that is, when the electro-motive force is 1 milligram and the current 1 new Ampère, or 1000 kilometers per second, the resistance in the conductor should be 1 unit, to be called Ohm. The units of electric work should be expressed in kilogrammeters or grammeters—that is, 1 kilogrammeter is 1000 grammeters.

The electro-dynamic notation for the above metric units should be as follows:

F = electro-motive force expressed in milligrams; that is, the available difference of electrical potential.

V = velocity of current expressed in 1000 kilometers per second, corresponding to what is now called Ampères, or intensity of current.

T = time of operation in seconds.

P = power in effects, or kilogrammeters per second.

$H.P.$ = horse power of 75 effects each.

K = work, expressed in kilogrammeters.

R = resistance to current expressed in Ohms.

ELECTRO-DYNAMIC FORMULAS.

Electro-motive force.

$$F = R\,V \quad \ldots\ldots 1$$
$$F = \sqrt{P\,R} \quad \ldots\ldots 2$$
$$F = \frac{P}{V} \quad \ldots\ldots 3$$

Velocity or intensity of current.

$$V = \frac{F}{R} \quad \ldots\ldots 4$$
$$V = \sqrt{\frac{P}{R}} \quad \ldots\ldots 5$$
$$V = \frac{P}{F} \quad \ldots\ldots 6$$

Time of operation.

$$T = \frac{K}{R\,V^2} \quad \ldots\ldots 7$$
$$T = \frac{K\,R}{F^2} \quad \ldots\ldots 8$$
$$T = \frac{K}{F\,V} \quad \ldots\ldots 9$$

Power in effects.

$$P = R\,V^2 \quad \ldots\ldots 10$$
$$P = \frac{F^2}{R} \quad \ldots\ldots 11$$
$$P = F\,V \quad \ldots\ldots 12$$

Horse-power of current.

$$H.\,P. = \frac{R\,V^2}{75} \quad \ldots\ldots 13$$
$$H.\,P. = \frac{F^2}{75\,R} \quad \ldots\ldots 14$$
$$H.\,P. = \frac{F\,V}{75} \quad \ldots\ldots 15$$

Work of current.

$$K = R\,V^2\,T \quad \ldots\ldots 16$$
$$K = \frac{F^2\,T}{R} \quad \ldots\ldots 17$$
$$K = F\,V\,T \quad \ldots\ldots 18$$

Resistance of current.

$$R = \frac{F}{V} \quad \ldots\ldots 19$$
$$R = \frac{P}{V^2} \quad \ldots\ldots 20$$
$$R = \frac{F^2}{P} \quad \ldots\ldots 21$$

This system will bring electro-dynamics down to the level of ordinary mechanics, and its units, nomenclature and notation will convey to the mind the real substance of the subject.—*Mechanics for November.*

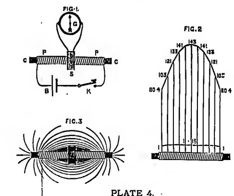

PLATE 3.

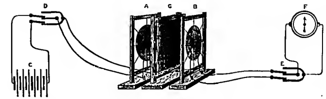

PLATE 4.

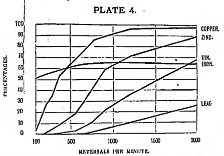

or flanges, or with thickened up pieces on either side or any part of their surface. "Armour-plates so made may be bolted together round their edges in the same manner as a cast-iron tank is generally made." "Or thicker parts are forged here and there on the armour plate, and the bolts are tapped into these thicker parts for fastening on the plates, so that the strength would be little or no less at the tapped part than at the other parts." Or projections similar to short bolts or studs may be formed on the inside surface of the plate, for fastening the plates to the skin of the vessel where there is no backing. Or where there is a backing this stud may be of little larger size, so that a hole tapped in its centre for receiving the screw bolt from inside for fastening on the plate will not pass beyond the ordinary surface of the plate, and therefore not weaken it. (Provisional only.)

THE PROGRESS OF ELECTRICAL SCIENCE.*

My first duty this evening is to thank you for the honour you have conferred upon me in electing me your president for the ensuing year. Knowing as I do the illustrious men who have preceded me as presidents of this society, I should not have presumed to accept so exalted a position had I not felt confidence in your kind indulgence, and in the assurance that the council would extend to me that kind assistance which they have ever been ready to render to my predecessors. This is but a young society, and necessarily so, for the branch of science in which we have enrolled ourselves as members is a very young shoot in comparison with many of the other branches of the same tree. Telegraph engineers and electricians have no great masters of antiquity to imitate or revere; most of their great men are of the present age. Since the formation of this society eleven presidential addresses have been given by such men, who have so thoroughly covered all the ground, and I might add the bottom of the sea also, that I feel a great difficulty in delivering to you the usual inaugural address, which is always looked forward to with so much interest by the members of this and kindred societies; for rapid as has been, and still is, the adaptation of electrical science to every-day life, were I to confine my remarks solely to the new matter which has been introduced since you heard the able address of the gentleman who has just vacated the position I now occupy, I am sure it would be as disappointing to you as it would be unsatisfactory to me. Still, it is not my intention to ask you to accompany me to speculative heights or theoretical depths, but rather to walk leisurely along the well-known

* Inaugural address delivered by Mr. Willoughby Smith, president, before the Society of Telegraph Engineers and of Electricians.

due to a spirit of conciliation which could do no harm; but if this sudden change of the character of the unit were done in the same spirit it might lead to inconvenience hereafter. To the practical electrician the material standard, not the definition, is the important point; consequently the next proposition—"That an international commission should be entrusted with the ascertaining by a new set of experiments for practical purposes the length of column of mercury, having a section of one square millimetre, at the temperature zero degree centigrade, which shall represent the value of the ohm"—was of more interest. The members of that commission met in Paris early in November last, and after passing several resolutions adjourned for twelve months. The adjournment is, I presume, to allow time for desired experiments; so that when the members re-assemble they will be prepared to publish their report, which, it is to be hoped, will embrace the whole question of units and fix them on a sound and lasting basis. In order to better illustrate the necessity of fresh measurements, I will direct your attention to Table I.

TABLE I.

Samples of Copper.	Conductivity.		
	First Test.	Second Test.	Third Test.
A	101·4	101·1	101·02
B	44·7	44·87	44·51
C	98·7	99·83	98·64
D	101·3	100·2	101·14
E	18·7	18·83	—

The figures show the specific conductivity of five samples of copper wire, assuming that of pure copper to equal 100, as given by Dr. Mathesson, viz. 100 inches of annealed pure copper, weighing 100 grains, has a resistance of 0·1516 ohm at 60° Fahr. The tests were made by three persons, each one making his tests quite independently, and by means of his own apparatus and method. The results show that with good apparatus and careful manipulation very accurate and reliable tests can be made. They also show what great differences there are in the specific conductivity of ordinary commercial copper, and confirm what I have already mentioned, that some commercial copper has a higher specific conductivity than the long recognised standard for pure copper. Late in the year 1837 Professor Faraday proved by actual experiment that different kinds of matter possessed different inductive capacities, and wrote of "The Specific Inductive Capacity of Dielectric Bodies." We of to-day use the same language, but our correct knowledge of the subject is very limited, and I believe a careful investigation of the whole matter at the present time would be most valuable. It is customary to consider the specific increase in its inductive capacity. Had more frequent tests been taken than are here shown, at temperatures varying from 32° to 100° Fahr., it would still have been found that each series would differ from the other in polarisation, resistance, and induction, and that the formula applied to one series would not be correct for any one of the others. To obtain accurate measurements in experiments of this kind it is essential that a constant electro-motive force should be employed, but unfortunately I know of no means by which such a force can be maintained; for although great and important improvements have been, and still are being, made in batteries, there has not yet, to my knowledge, been produced one that combines all the essential elements of constancy.

If it were necessary numerous instances might be given to show how slow the human mind is, and always has been, to comprehend and utilise the rich and wonderful gifts which nature is constantly casting before it. Thales 2,400 years ago is said to have discovered what we now term the electric qualities of amber, but it was not until the seventeenth century that this phenomenon began to attract public attention, and, under the keen observations of the philosophers of that time, to rapidly develop into a science. To the alchemists of the sixteenth century belongs the honour of having first noticed the change which took place in silver chloride by exposure to light; but photography, which sprang from that very fact, is but of very recent date. It is now nearly ten years—alas! how swift is time!—since I first called attention to the wonderful effects light, and especially solar light, has on the electrical qualities of selenium; but to the present time we have not been able to realise any one of the results which, I feel sure, will ultimately arise from it; for where there is absorption of light, whether of dark or visible rays, by any body, work of some description must have been performed in that body. Of all the endeavours to utilise this property of selenium the photophone appeared the most promising; but knowing what I did of the behaviour of selenium, I was not sanguine of its application for the purpose proposed, for as electricity acts by what we know as induction on a dielectric, so does the action of light act on selenium, that is to say, it absorbs slowly, and as slowly gives it back. My meaning will perhaps be more intelligible by reference to Plate I (see page 493). A bar of selenium in a small room from which all light was excluded was connected by means of insulated wires to a battery of one hundred cells and an astatic mirror galvanometer in an adjoining room. The vertical figures represent the ratios of the galvanometer deflections obtained. While the light was excluded the deflection remained quite steady for ten minutes, as shown at A, but on exposing the bar to the light from an ordinary wax candle placed one metre from the bar the deflection immediately increased from 1 to 1·4 and then continued slowly increasing until at the end of ten minutes it reached 1·45, as shown at B. Immediately

ELECTRICITY, ELECTRO-MAGNETISM AND EFFECTS.

When in 1752 Benjamin Franklin by means of his kite and wired string attached thereto brought sparks of electricity from the clouds during a thunder storm, that scientist, philosopher, journalist and statesman declared that some day this subtle fluid electricity, would be a power which would be an immense factor in the affairs of man, when we had learned how to manipulate and control it, and he then invented and proved the efficiency of the lightning rod almost as it is to-day. Since his experiments but 133 years have gone by, and already Franklin's predictions are verified. The Morse telegraph in 1844 astounded the world by speeding messages across the country with the rapidity of thought almost; and his science is now so perfected that a telegram can be transmitted around the earth, about 25,000 miles, in three minutes. Following quickly upon the heels of telegraphy came the discoveries of Professor Farraday and others in the science of electricity and electro-magnetism.

Then came Edison, our modern magician, whose powerful wand quickly revealed new wonders. Not only has he taught us to apply the mysterious power of this subtle fluid, for the practical benefit of mankind in multitudinous ways, but he has also developed innumerable resources of electricity, many of which are practically applied. After the sensation created by the Morse telegraph mankind did not seem to wonder much at later methods of employing electricity in every day affairs of life, so that even the telephone stepped into its place of usefulness without attracting very great attention, and was not a nine days' wonder even to the progressive civilized world.

The electric light, so commonly used for illuminating purposes, is no new thing so far as discovery is concerned. Its production and quality have long been taught and demonstrated in high schools and colleges, where the necessary philosophical apparatus is a part of the outfit. The dynamo is but an ordinary battery, run by steam, to continuously generate the fluid. The question with which the electricians of to-day had to deal was that concerning carbon points, and, while they have so far succeeded in this as to be able to evolve light successively from a set of points, yet are there many improvements needed, and will doubtless be made ere the electric light is a grand success.

As it is, however, the telegraph, telephone and electric light wires stretch over a large portion of the globe, often in unbroken chain for thousands of miles. Along railroads, highways, rivers and canals are strung the inevitable wires for the transmission of thought and voice. The cities are occupied by vast net-works of these lines, making so many conductors for the free and ready passage of this powerful agent of nature, so little understood even yet as regards the causes of its production, its transmission, or its laws.

Strange atmospheric phenomena, unusual storms, cyclones and other disturbances of the air and our surroundings are on the increase, and strangely enough in about the same ratio as have increased the numbers of telegraph, telephone and electric light wires. Is not the cause of these strange effects to be herein found? In chaining the lightning have we not undertaken to curb and tame a monster of power which may compass our destruction? May it not be the reason of our climatic changes and fearful tornadoes? Scientists are paid to attempt the solution of these problems, and it is to be hoped they may speedily master everything concerning electricity. All nature is pervaded with it, and the world ought to know everything about this natural dynamic whose power is inconceivable. Late freaks of electricity during severe cyclones have caused the total demolition in some places of telephone wires and boxes, and the destruction of every species of property near by. A full understanding of the subject will undoubtedly be made, and we be enabled to apply proper remedies for preventing disastrous effects.

Transmission of Power

34

Transmitting Power by Electricity.—Time will probably reveal to us effectual means of carrying power to great distances, but I cannot refrain from alluding to one which is, in my opinion, worthy of consideration, namely, the electrical conductor. Suppose water-power to be employed to give motion to a dynamo-electrical machine, a very powerful electrical current is the result. This may be carried to a great distance, through a large metallic conductor, and there be made to impart motion to electro-magnetic engines to ignite the carbon points of electric lamps, or to effect the separation of metals from their combinations. A copper rod of 3 in. in diameter would be capable of transmitting 1,000 horse power a distance of, say, thirty miles, an amount sufficient to supply one quarter of a million candle power, which would suffice to illuminate a moderately sized town. The use of electrical power has sometimes been suggested as a substitute for steam power; but it should be borne in mind that so long as the electric power depends upon a galvanic battery it must be much more costly than steam power, inasmuch as the combustible consumed in the battery is zinc, a substance necessarily much more expensive than coal. But this question assumes a totally different aspect if in the production of the electric current a natural force is used, which could not otherwise be rendered available. 77

Direct Conversion of Mechanical Work into Electricity.—M. E. Guignet.—The Polytechnic School of Rio Janeiro possesses an electro-motor formed of five fixed electro-magnets, and of a movable drum furnished with six bars of soft iron. The current of ten Bunsen elements being passed along the wire of the electro-magnets the drum revolves quickly. This apparatus has long been employed to show how a current of electricity, whatever its origin, may act as a motive power. The same apparatus may serve for the inverse demonstration. If the two ends of the wire of the electro-magnets are connected with a galvanometer, and if the apparatus is turned by hand, a continuous current is produced. 77

Siemens's Electric Railway.—As the next meeting of the Iron and Steel Institute will, at the end of August, be held at Dusseldorf, many readers will have an opportunity of seeing this railway, which has been laid in that portion of the Exhibition Grounds, near Krupp's Pavilion.

Electrician May 22 1880

ON THE ECONOMIC DUTY OF ELECTRIC MOTORS, AND THE MEASUREMENT OF THE QUANTITY OF ENERGY TRAVERSING AN ELECTRIC CIRCUIT.

BY M. MARCEL DEPREZ.

[Translated from the *Comptes Rendus.*]

When a motor is inserted in the circuit of a battery, the intensity of the current differs when the motor is inactive and when it moves with the production of a certain quantity of work. Let I be the current when the motor is at rest, and i the current when it is in action. After measuring these two values let us stop the motor and introduce in the circuit a resistance such as will reduce the current from I to i. Under these conditions the production of energy by the battery is evidently the same as when the motor was at work; since the electromotive force and the current are the same. Moreover the expenditure of energy evidently has not varied in that portion of the circuit external to the motor and to the additional resistance. We are therefore justified in stating that, in regard to expenditure of energy, the motor in action on the one hand, and the motor at rest, with the additional resistance, on the other hand, are precisely equivalent.

Now the quantity of energy absorbed in a simple resistance and converted into heat, in unit time is expressed by the product of the resistance into the square of the intensity of the current.

Calling r_1 the resistance of the motor at rest, r_2 the additional resistance necessary to reduce the current to the intensity i, and Q the quantity of heat evolved in these two resistances, we have

$$Q=(r_1+r_2)\,i^2.$$

In accordance with what precedes, this is also the quantity of energy manifested as heat and work, absorbed by the motor when it is in action. Calling T the work here referred to, we have

$$T+r_1\,i^2=(r_1+r_2)\,i^2,\text{ or }T=r_2\,i^2.$$

Comparing this portion of energy converted into useful work with the total quantity absorbed by the motor, we obtain an expression for the duty:—

$$\frac{T}{Q}=\frac{r_2}{r_1+r_2}.$$

This very simple expression may be replaced by another, which is of great importance in the case where the current is produced by a dynamo-electric machine. Let us call $E_{\prime}$ the electromotive force of the generating machine and E the opposing E M F of the receiving machine, which, by the effect of its rotation, tends to generate a current in the direction contrary to that of the working current. The current traversing the two machines is due to the difference $E_{\prime}-E$; and if we call R the sum of the *static** resistances of the two machines and of the external circuit it will be expressed by

$$I=\frac{E_{\prime}-E}{R}.$$

Let us now find the value of the resistance r_2, which must be added in the circuit in order that the current traversing it may still have the intensity I, when the rotation of the receiving machine is arrested. This is obtained from the equation

$$\frac{E_{\prime}-E}{R}=\frac{E_{\prime}}{R+r_2},$$

whence

$$r_2=\frac{E_{\prime}R}{E_{\prime}-E}.$$

The value of the absolute economic duty of the receiving machine will be equal, in accordance with the preceding theorem to $\frac{r_2}{r_1+r_2}$, in which the total resistance, R, of the whole circuit should be substituted for r_1.

* [The author explains in a foot note that he means by this the resistance of the machines in a state of rest. We should prefer the expression "wire resistance," or simply "resistance;" since at a given temperature the resistance, properly speaking, is constant, and quite independent of any opposing E.M.F.—Ed. E.]

value,

$$\frac{E}{E_{\prime}},$$

a remarkable expression, which is independent of the resistance of the external circuit.* This fact may at first sight seem extraordinary, and even contradictory to certain experiments in which perhaps sufficient care was not taken to realise the conditions of maximum duty. It becomes less paradoxical when it is remembered that whenever a current is employed to develop energy in a form other than mechanical work, for instance, to produce the decomposition of water in a voltameter, the number of equivalents of water decomposed is always equal to the number of equivalents of zinc dissolved in each of the elements of the battery, whatever may be the length of the external circuit. The latter, moreover, does not affect the number of elements necessary to produce this decomposition. We have therefore a well-verified experimental fact in which the economic duty is not influenced by the external circuit.

I pass now to the description of the apparatus allowing of the measurement of the quantity of energy passing during unit time electric circuit included between two points, A and B.

Let us unite these two points through an auxiliary (derived) circuit of high resistance, in which is inserted a galvanometer coiled with a long and fine wire, whilst another constructed with a short and thick wire is placed in the main circuit. This being understood, let us endeavour to find the expression for the quantity of energy passing in the principal circuit in terms of the intensities of these two currents, measured by the deviations of the galvanometer needles.†

Let us call I and R the intensity and the resistance of the main circuit, $I_{\prime}$ and $R_{\prime}$ the corresponding values for the derived circuit. Let E be the difference of the potentials at A and B. The quantity of energy passing in the main circuit is expressed by RI^2 or EI; whilst the intensity of the current in the derived circuit is

$$\frac{E}{R_{\prime}}=I_{\prime},$$

whence

$$E=R_{\prime}I_{\prime},$$

and, consequently,

$$EI=R_{\prime}I\,I_{\prime}.$$

The quantity of energy is therefore proportional to the product of the intensities of the two currents, or to the product of the deviations of the needles.

An instrument may be constructed which will indicate at any time the value of this product.

depth to allow the rope to sink beneath the surface of the periphery of the wheel are invariably preferred. As, however, the returning side of the rope is as much slackened as the working side is tightened, it is advisable to so arrange the pulleys and driving wheels that the tight or driving side of the ropes is at the bottom, by which means the returning or slack side of the ropes is made to lap round the upper part of the pulleys, and bearing surface is thus obtained which would be lost if the slack side ran from the bottom. In the majority of mills where rope gearing is employed, power is taken off both sides of the driving pulley, and then the ropes on one side must obviously drive from the top; but the disadvantage is probably compensated for by other advantages. It is believed that the friction of rope-gearing, especially at high speeds, is considerably less than that of toothed wheels; but on this point, amongst some others, information is wanted. Comparing ropes with belts, it is calculated that a rope 6½in. in circumference does as much work at a given speed—say 3,000ft. per minute—as a 4in. leather belt. The bearing surface of the rope on a 4ft. 6in. pulley will be 85in., or half of the circumference; and allowing the rope to be in contact with the pulley for a width of half an inch on each side, the total bearing surface will be 85in. With a leather belt 4in. wide, it would be 340 square inches, or four times the amount. To obtain equal results, therefore, the effective pressure of the rope per square inch of bearing surface must be four times that of a belt. The few experiments that have been made show that ropes in a V-shaped groove have a much greater effective pressure per square inch of bearing surface than belts. The results of experiments made with different sizes of ropes, and not always in grooves adapted for them, however, were so discordant as to render it impossible to arrive at any definite conclusion as to the proportion between the friction of ropes and belts. It is known from the experience of ordinary working that the ropes are superior to the spur or bevel wheels, and equal, at least, to leather belts in steadiness of driving and all that the engineer aims for, while they are much cheaper than either in first cost and maintenance—the annual cost of ropes being only about £5 per 100 indicated horse-power. Possibly the largest mill driven by ropes is the Samnuggur Jute Factory, at Calcutta, where the engines are of 1,000 indicated horse-power, making 43 revolutions per minute. The fly-wheel is 28ft. in diameter, and 6ft. 7in. wide, the peripheral velocity being 3,781ft. per minute. The 25 ropes transmit 40 horse-power each, and have thus a tension of 349lb., the result of the experiment, which there was some hesitation in making, owing to a want of knowledge of the effects of the warm and humid climate, having been most satisfactory. At North Oakland, in California, a manufactory has been recently established for the construction, on a large scale, of gut ropes. The entrails of sheep, which average about 55ft. in length, are pickled in brine, and twisted into ropes or plaited into belts. It is said that the ropes thus made will last 10 years, whereas good hemp ropes do not average much over three years, though ropes used for driving-gear have been known, according to Mr. Durie, to last 10 years and a half. The great advantage of gut ropes, however, would appear to be in their enormous strength compared with their size—a cord three-eighths of an inch in diameter withstanding a strain of about 4 tons. Belts will still hold their place for certain work in a factory, to which their shape renders them specially adapted; but for driving shafting we may now expect to see ropes come into very general favour.

THE TELEMACHON.—Another new name in mechanics has been required by the invention of Mr. William Wallace, of Ansonia, Conn., who claims to have devised an electro-dynamic machine whereby power can be transmitted to any distance by electricity. This apparatus has been termed the "Telemachon." In the Wallace instrument no battery is used to produce the electricity. The current generated by his electro-dynamic machine is carried by two copper wires to the Telemachon. This converts the electricity into mechanical power. It consists of electro magnets and revolving armatures. The electro magnets are so arranged that they attract the poles of the armature, causing it to move. Each new position brings pieces in contact with a spring, which causes a re-distribution of the magnetism. Again, attraction takes place as before, and again the direction of the current is changed by the break-pieces. The magnetic effect being repeated, the rotation is continuous, increasing constantly in speed until the friction and the magnetic power balance each other, the machine being able to make 3,000 revolutions a minute. Dec 78

The electricity from the Telemachon may be applied to illumination. It solves the problem of the division of electric lights. Both the Wallace foundry and the Farrel foundry, near by, are illuminated by these lights, the army of men being formed in two divisions, one working during the day and the other up to midnight. Thickly studded as these foundries are with heavy machinery, and obstructed as the light must necessarily be by the ponderous cranes, drills, supporting columns and projections, a clear light is thrown upon the machinery, perfectly illuminating it. Adjustments to the 32d part of an inch may be made without the least strain upon the eyes. A beautiful effect of this light is its polarization—that mottled appearance which it assumes when falling through glass. This is the only artificial light, it is said, that is capable of producing it.

It is claimed that Mr. Wallace has succeeded in transmitting power from the Naugatuck river to his factory, a distance of a quarter of a mile, and that the power of this stream is sufficient to run the machinery of the Wallace factory, where three hundred men are employed. It is claimed that experiments show only about 10 per cent loss of power by the transmission.

CAN WE TRANSMIT POWER IN LARGE AMOUNT BY ELECTRICITY?*

By N. S. KEITH, Newark, N. J.

THIS question is suggested by a statement made by Dr. Siemens, widely printed in the journals of the day, that a continuous rod of copper thirty miles in length and three inches in diameter is capable of conveying that distance, electrically, energy equal to 1,000 horse power. It is not attempted to advance the statement that the source of power shall be zinc, nor even coal, but waterfalls, which from their situation are not practically available for manufacturing establishments in their immediate vicinity.

In order to fully consider this subject, we must understand the doctrine, I may say the science, of the correlation of the the forces, so called. We must understand that all matter is endowed with an amount of FORCE, and that each atom and molecule, simple and compound, has its specific portion of the whole. This force, at rest, is called latent heat, intrinsic energy, or potential. In motion it is called heat, light, electricity, chemical affinity, attraction, magnetism, power, etc., according to its sensible manifestations. These are the effects of the one force in motion in different substances, or in different assemblages of matter. Force put in motion comes to rest by reason of the resistance to motion which it encounters; in overcoming of resistance the manifestation is sensible heat. Each of these manifestations of force is convertible to one or all of the others, and they are all caused by some mode of motion. Force may be illustrated by a spring under tension, or by a suspended weight. Release the spring and weight, and they give off as much force or energy as was used in setting up the tension of the spring, and in raising the weight perpendicularly the length of its fall. Any of these forces then may, figuratively speaking, release the weight and spring.

While there is but one electricity, there are two conditions of it, namely, *static*, which is electricity at rest but under high tension, and *voltaic* electricity or *galvanism*, which is a mode of motion. It has but one cause, and that is force, or matter in motion. Yet we, for perspicuity, call electricity by friction, *static* or *frictional*; electricity by chemical affinity, *chemical* from its immediate cause, or *voltaic* or *galvanic* from its discoverers; electricity by magnetism, *magnetic*; electricity by heat, *thermic*; electricity by mechanical power, *dynamic*.

As chemical and thermic electricity have too costly sources for our purpose, we must consider the magnetic and dynamic.

Now that we have learned what electricity is, we must understand what it is not. As an entity it does not exist; it is a signification simply. When we comprehend it as a condition or quality of matter in self-containing motion, not as a current or flow of something through matter, we will be able to deduce facts in the science, and sustain them by practical illustration. The first conception by the mind of a force or motion having its source within a circuit, and manifesting itself at all parts thereof, is that of a current or flow of something. The probability is, electric current is molecular change of form caused by tension upon the atoms composing the molecules in the direction of disrupting them. There is certainly a change of dimensions of matter subjected to electricity, as there is with heat and magnetism. This change of form causes friction of adjacent molecules and its resultant heat. This heat is the exact equivalent of the energy causing the electric current. Energy, when used as electricity, is called *electromotive force*; this varies in degree with its tension, as in case of its illustration by a weight in suspension or by a spring. Some use the term *intensity* to express the same. The tension of a spring may illustrate the electromotive force of static electricity, which imparts its charged energy with a single impulse. A suspended weight released increases its speed each foot of fall, and consequently its force and effective quantity. So with voltaic electricity: each cell in circuit increases the speed and quantity of current. In case of dynamic electricity, each increment of circuit receiving electric impulse adds to speed and quantity of current.

All matter offers an amount of resistance to changes of form or arrangement of molecules, whether by heat, electricity, magnetism, or any other of the forces. This resistance is specific for each substance. The specific resistances opposed to electromotive force have been tabulated relatively in the cases of metals common in the arts, and with the important alloys. The metals are the best conductors, or, in other words, offer the least resistance. These follow solutions of binary salts, other liquids, *et sequentes*. Copper and silver offer the least resistance, are relatively alike, and are graded as ¼ in scale of resistances. Iron offers nearly six times the resistance of copper, and is graded 5·95. Heat increases the resistance of metals to the extent of about 0·2 of 1 per cent. for each degree Fahrenheit rise in temperature.

Electricians have a formula which sets forth Ohm's law. This is that the current (sometimes called quantity) of electricity is the result obtained by dividing electromotive force by resistance; thus, $\frac{E}{R} = C$.

The unit of electromotive force is called a *volt*, in commemoration of Volta, the inventor of the voltaic pile. It is very nearly represented by the electromotive force, or energy, or intensity of a Daniell cell. The unit of resistance is called an *ohm*, after Ohm, who laid down the law. A wire of pure copper 0,040·5 feet in length and ¼ of an inch in diameter has a resistance of one ohm. The unit of current or quality is called a *weber*, or *veber*, after Weber, another investigator in the line.

A veber of current represents the energy set free by the combustion of 11 grains of carbon, or 11 grains, about, of coal, or 1 grain of hydrogen, with a development of 6 units of heat in 6,338 seconds. That amount of free or sensible heat is set free in the circuit. Thus, one volt of electromotive force forces one veber of electric current through a circuit of one ohm resistance, requiring to do so 4,673 foot pounds of energy, with a development of 6 units of heat in the circuit in 6,338 seconds. The heat set free is the exact measure of the force used.

If we pass this veber of current through a solution of copper sulphate, the electric equivalent amount of metallic copper will be deposited, namely, 31·75 grains in the same time. Now, if we increase electromotive force by adding another cell to the circuit, making electromotive force 2, and so regulate resistance that it remains one ohm, a current of 2 vebers passes in the same time, thus: $\frac{2E}{1R} = 2C$.

Now, we find that twice as much zinc is consumed in *each* cell, or four times as much in the circuit, or its equivalent in energy is used in depositing only twice as much copper. We have in the circuit four times as much heat, which is the measure of the energy expended. Chemical decomposition is the measure of current, while heat is the measure of electromotive force multiplied by current. Increase electromotive force to 3, keep resistance 1, and we have a current of 3, and nine times the energy expended, resulting in nine times the heat.

It is now to be seen that by increasing definitely the amount of electromotive force, and at the same time keeping resistance as low as possible, we may use a definite amount of energy and distribute it as heat throughout the circuit in proportion to the special resistance of its parts, and utilize it as mechanical power. The object of increasing E at the expense of C is that we may save in weight of copper constituting the conductors. We get the energy distributed throughout the circuit, though but the square root of it is shown in chemical action when measured by the amount of copper or other metal deposited in a single depositing cell.

If we magnetize a core of soft, uncarbonized iron within a coil of copper wire by bringing it into the magnetic field of an electro or a permanent magnet, at the instant of stoppage of motion a current of electricity will start in the coil in one direction; that is, the molecules composing the circuit will turn in one direction, and then the action ceases. Remove the core and coil, a reversed current starts and continues as long as motion lasts in removing them from the field. If we revolve this arrangement between the poles of a magnet, thus alternately magnetizing and demagnetizing the core, we will get a succession of discharges of magnetism through the copper coil utilized as electricity. While the core is acquiring magnetism, there is no current in the coil, as there is no magnetic resistance to motion which requires force to overcome. As soon as it begins to lose magnetism an electric current is induced in the coil, which we may cause to do work by proper mechanical appliances.

We will find that the coil and core are heated, and the amount of heat is the measure of the mechanical force used, less that due to friction of the journals carrying the arrangement. If the coil completes the electric circuit within itself, so that there is no external resistance, then the total heat will be developed therein. If the circuit is made com-

-OVER

6

plete by a conductor, then the heat will be divided between the coil and conductor in proportion to their respective resistances. If this conductor be the coils of an electro-motor, the heat due to it can be utilized as work, less loss by conversion.

We have now the general requirement laid down, so will proceed to plan and construct a theoretical machine to suit the requirements of 1,000 horse-power, to be transmitted, if possible, through a rod of copper thirty miles in length and three inches in diameter. As resistance of wire of same diameter is in direct proportion to its length, and as we have seen that 0,040·5 feet of copper wire, ¼ inch in diameter, has a resistance of 1 ohm, so 30 miles, or 158,400 feet of ¼ inch wire, has 20 ohms resistance. But as it also decreases in proportion to the square of the diameters, we figure in the 3 inch rod a resistance of ·18 ohm, if of pure copper, at a temperature of 60° Fahr.

The energy of 1,000 horse-power is measured as 33,000,000 foot pounds per minute, and that of one veber current equals 4,073 foot pounds in 0,338 seconds, or 44·24 foot pounds per minute. So it will require 740,000 vebers current, or their equivalent in energy, to utilize 1,000 horse-power as electricity for dynamic purposes.

We may therefore use electromotive force of 1,000 volts, resistance of 1·34 ohms, and a current of 740 vebers; thus, $\frac{1{,}000\ E}{1{\cdot}34\ R} = 740\ C$. In other words, the dynamic equivalent of 740,000 vebers may be had by multiplying the electromotive force 1,000 by the current 740.

It has been found that a discharge of the magnetism of a soft iron core induces a current in the coil surrounding it possessing electromotive force of one volt for about each twenty-five feet of coil. The quantity or current comes from the strength of the magnetism and number of discharges. For 1,000 volts electromotive force we will take 25,000 feet in length of copper wire or strips, weighing 1·2 pounds per foot length, or in all 30,000 pounds. This will have a resistance of ·60 ohm. It should be wound upon a core of iron weighing 10,000 pounds. This core and coil, constituting what is called an armature, must be revolved between the poles of an electro-magnet having such an attraction for the armature as to call for the expenditure of 1,000 horse-power in revolving it. Such a magnet will weigh, probably, 60,000 pounds, and have a like weight of copper in its coils. It should be excited or magnetized by a smaller armature revolved between the poles of a smaller magnet, with an expenditure of, say, 100 horse power. This is necessary, because, if the coil of the magnet is part of the main circuit, the resistance will be much increased.

The electro-motor receiving the current of electricity must have at least the same length of copper in its coils; and as the resistance of the coils (when the machine in motion is exerting its greatest power) is double that which they have at rest, and as it is necessary from our other fixed resistances to make the resistance of the machine ·50 ohm, we make the weight of copper coils per foot 3·17 pounds, a total of 70,200 pounds, with a weight of iron about 70,000 pounds.

The cost of this apparatus will be as follows:

Exciting magnet and armature.....................	$3,500
Large magnet, 60,000 lb. iron, including work thereon, 10c. per lb..........	6,000
60,000 lb. copper, 60c. per lb....	10,000
Armature: 10,000 lb. iron, and work thereon, 10c. per lb.........................	1,000
3,000 lb. copper, 30c. per lb.	9,000
Brass bearings, brushes, etc...................	2,500
Total for machine.................	$40,000
Conductor: 158,400 feet copper rod at 27½ lb. per foot, 4,350,000 lb., 30c..........	$1,300,800
Ground plates and connections.....	5,000
Insulation, etc., indefinite, say	100,000
Total for conductor.........	$1,411,800
Motor: Iron and work, 70,000 lb., 10c..........	$7,000
Copper, 70,000 lb., 00c..........................	23,700
Brass, brushes, etc...........................	2,500
Total for motor	$33,200

The energy of 1,000 horse-power expended on the machine generating the electric current is distributed throughout the circuit in proportion to the special resistances of several parts. The armature, having a resistance of ·60 ohm, absorbs 66·134 or 462·5 horse-power; the conductor 18·134 or 131·3 horse-power; the motor 50·134 or 378·2 horse-power. This last amount is all that can be utilized with this arrangement, even if there is no loss. We may make our electric machine and the motor larger, or place two of them, making the resistances of them one half as much, but not with any increase of utilizable power, as the resistance of the conductor remains the same.

Let us consider a resistance of ·73 ohm for machine, ·18 ohm for conductor, and ·25 ohm for motor, and we have 33·76 or 454 horse-power for machine, 18·76 or 237 horse-power for conductor, and 25·76 or 329 horse-power for motor. This is less available power than before. The resistance of the earth returning the current we may count as nothing. Under no circumstances can we utilize the full power expended.

If we decrease the resistance of the machine to ·33 ohm, and increase that of the motor to ·84, keeping total resistance the same, we will gain. Then the machine will absorb 33·131 or 246·2 horse power; the conductor 18·131 or 143·3 horse-power; and the motor 610·5 horse-power. With a larger conductor or shorter distance, this proportion may be increased.

There are various sources of loss, especially with electricity of such electromotive force and tension. I have no doubt that at least 50 per cent. of the energy expended on a magneto-electric or dynamo-electric machine at a waterfall may be used at a distance by an electro-magnetic motor as mechanical power.

The amount of heat developed throughout the entire circuit will be equivalent to that from the combustion of 200 lb. of coal per hour, or 42·746 heat units per minute. The proportion due to the armature, having resistance of ·33 ohm, is sufficient to raise its temperature one degree Centigrade per minute. Of course, then, some arrangement for cooling by water must be applied.

What the effect of a discharge of a portion even of this current, with its high tension, through the body of a man would be, I leave you to imagine. Probably it would be worse for that man than it was for the one who was kicked by the Kentucky mule; "they swept up the pieces" in that case, as the veracious reporter states.

TRANSMITTING POWER BY ELECTRICITY.

The Société du Val d'Osne has an electro-plating establishment in Paris, where a process of coppering cast iron is carried on. The source of electricity is a Gramme machine, ordinarily run by a special engine at considerable expense and trouble, as it was situated at considerable distance from the main motor. M. Cadiat suggested the use of two Gramme machines, one to be connected to the driving shaft of the works, and to produce a current which should set machine No. 2 in motion, and this in turn might drive the machine which supplied current for the baths. Motive power was thus transmitted over a distance about 400 feet by means of a single copper wire. The system, says M. Cadiat, in *La Nature*, has worked perfectly and uniformly for two months. The velocity can be easily regulated by interposing resistance in the circuit. If, in the circuit from machine No. 2 to the electro-plating machine, a copper wire 6·4 feet long and 0·06 inch in diameter be inserted, the velocity falls from 750 to 40 turns per minute; with an iron wire 4·8 feet long and 0·32 inch in diameter, the velocity is reduced to 100 turns. As for the power required, the author states that the starting or stoppage of the system is not recognizable by the engineer who controls the driving engine of about 10 horse power, from which power is also taken for a variety of tools.

July 78

UTILISING NIAGARA.—Some months ago the *Buffalo Commercial* described a series of experiments made in this city with the view of demonstrating the practicability of using the immense water-power at Niagara Falls for transmitting power to this city through the agency of compressed air. The experiments were sufficiently successful to convince several of our enterprising citizens that the scheme was entirely feasible. A company has since been formed, of which Senator Pierce is president, considerable capital has been paid in, and practical operations have been begun. The principal part of the machinery will be near the water's edge, below the falls near that delightful spot called the Bridal Veil. The rest will be on the bank immediately above. The great air receptacles, three of which will be 70 feet long by 6 feet in diameter, will be below the bank, near the water; while the receiving reservoirs will be on the bank. The cylinders will be constructed of boiler iron in the most substantial manner. The perpendicular fall from the feeding basin above to the air receptacles below is 214 feet. The engineer's figures show that 200,000 lb. of iron will be required, and it is estimated that power enough will be generated to raise about 350,000 gallons of water 150 feet every minute. These results have been obtained by careful scientific tests, so that there is little doubt but they are nearly correct.

July 18

IN reference to the statement that Sir William Armstrong has employed electricity, generated by water power, a mile and a half distant, to light his picture gallery, and that he proposes to use the same force to turn machinery about his house, Mr. D. R. Jones sends us a copy of a letter sent by him to the *Australasian*, October 25, 1870, in which, referring to the phenomena of dynamic electricity, he states that it is evident that motion may be transformed into electricity, and *vice versâ*. He suggests that we may have here "the means of utilising the motions of the air and of water, which, for want of means of transmission, have been hitherto allowed to run to waste. Various methods of converting, transmitting, and utilising force will readily suggest themselves as a combination of these well-known facts. While we have such superabundant constant supplies of force it is not right that the stores of Nature should be ramacked."

78

THE TELEMACHON. — By his electric telemachon, Mr. William Wallace, electrical manufacturer, of Aosonia, Conn., U.S., is enabled to transmit power from the Naugatuck River to his factory, a quarter of a mile off, with a loss of some 20 per cent. of the current. The telemachon consists of a dynamo-electric machine, for transforming mechanical power into electricity, and an electric motor, which reverses this operation, and turns the current into power. It is this apparatus that Edison alludes to in his account of his ... with the electric light. As it exists at present, Mr. Wallace's dynamo-machine only feeds eight separate electric lights, each being reputed to equal 4,000 candles.

The Siemens Scheme for Transmitting Power by Electricity Criticised.

THE scheme for transmitting power from natural waterfalls by electricity, as propounded by Dr. Siemens in his celebrated Glasgow lecture, is rather severely criticised by a writer (Mr. J. T. Sprague) in the *English Mechanic*. We extract from Mr. Sprague's article the summing up.

Dec 15/78

Mr. Siemens says, correctly, that "the conductor itself (which includes also the generating machine) retains a certain amount proportional to that transmitted. That is to say, the engine must expend 1000 horse-power to transmit 400." This assumes, too, perfect conditions, no loss in the transformations of energy, no leakage on the road. Hence this figure would probably be doubled in actual operations. It is needless to go into the 1000-fold figures, as the proportionate loss remains the same.

Further on Mr. Siemens refers to his proposal to transmit "1000 horse-power a distance of 30 miles through a conductor 3 inches in diameter. The electrical resistance of this conductor would be ·18 of a unit, and, supposing that the total resistance in circuit was made 2·5 units, which, as I before stated, gives a favorable working condition, it follows that

$$\frac{\cdot 18}{2 \cdot 5} \times 1{,}000 = 72 \text{ horse-power}$$

would be expended in heating the conductor. This would represent about 15 lb. of coal per hour—a quantity quite insufficient to raise a mass of 1900 tons of copper, with a surface of 132,000 square feet, to a sensibly-heated condition."

This refers to the potential heat of coal, supposing it were all transferred to the copper. But it is desirable to consider what would become of the machine developing the power. We have :—

Total resistance	= 2·5
Conductor ·18, machine 1	= 1·18
Resistance of useful work	1·32

Now, assuming that we are to develop 1000 horse-power in this 1·32 resistance, we have :—

Useful work 1·32	= 1000 h.-p.
Heat in conductor ·18	= 136·36
Heat in machine 1	= 757·57
Horse-power expended	1893·93

Here, again, we leave out of consideration all loss in conversion and leakage, and this would probably double the amount.

It appears, then, that having a free gift from nature in a waterfall 30 miles away, to utilize it as 1000 horse-power we must provide :—

1. Dynamic converters, capable of developing 1000 horse-power.
2. 1900 tons of copper rod, properly insulated.
3. A dynamo-electric apparatus capable of generating a current representing at starting 2000 horse-power.
4. Means of cooling that machine, and dissipating rapidly a constant energy equal to 758 horse-power.

It becomes a very serious question whether it would not be desirable to look that gift-horse (power) in the mouth. Without going into figures it really seems that it would be cheaper to buy steam or gas engines, and pay for coal to do the work on the spot.

Transmission of Power at Rock Island Arsenal. Feb. 22/79

The experimental line of water power machinery with cable transmission, devised by Col. D. W. Flagler, for the Rock Island Arsenal, is said to work admirably. The full plans of Col. Flagler embrace 40 65-inch turbine wheels, working on two separate shafts, 20 wheels to a shaft. But now only four of these turbines are in place; the shaft is 9 inches in diameter, and 100 feet long. On the shore end of the shaft there is a driving pulley 15 feet in diameter, which receives a wire rope three fourths of an inch in diameter, which ascends to a tower and continues on to the shops. There are six spans of transmission, each span 400 feet in length, making the distance from the dam to the south row of shops 2,400 feet, almost a half mile. The ends of these spans are station towers of trestle work, each 40 feet high, these stations consisting of receiving and driving pulleys, each 15 feet in diameter. On one of the towers the cable turns at right angles by means of bevel gears. The four turbine wheels now being tested yield 240 horse power; and there was not a hitch in the whole length of the cable and machinery. This force will be used this winter for the shops. The great dams, the water power canal, and the minor parts of the work, have cost about $1,000,000. The pen stock is entirely of iron; and the turbines are so placed on the shaft that the stoppage of one by driftwood or otherwise will cause no derangement of the others.

TRANSMISSION OF POWER BY ELECTRICITY.—Profs. Houston and Thomson have experimentally shown at the Franklin Institute that powerful electric currents can be conducted by very fine wires. They sent the current generated by one dynamo-electric machine through a wire ·004 inch in diameter to a second machine, which, working reversely, gave off considerable power. Apr. 79

Endless Ropes for Rapid Transit.

Mr. Hausknecht, the inventor of the absurd rapid transit plan which we noticed in our last number (page 102), sends us a letter in which he expresses his utter disgust at what he calls our "absurd editorial." He says: "My circular presents two practical, separate plans, and describes their mode or manner of operation, which must not be mixed up like an Irish stew, showing that the editor does not understand them," etc.

To this we remark that our account is no more mixed up than the inventor's own circular, from which it appears that he wants to use compressed air to raise the cars to the top of the inclines of "25 feet fall to the mile, by which they will attain a speed of about 20 miles per hour by the law of gravity," . . . "utilizing the force of speed, it will run up a part of the hight it has come down, rear car striking against truck platform to stop. The conductor presses his foot on rope lever, opens lower valve, admitting compressed air into cylinder, driving piston connected with four-wheeled truck, car riding thereon, upwards on inclined rails, delivering car automatically to the next section; the conductor pulls the rope, shuts the valve, the used air escapes, permits the truck to descend, in readiness to receive succeeding car, when he is on his way to next station; time consumed, say one quarter of a minute."

The circular further states: "The endless rope system is automatically to connect with the inclined plane system, but is intended for steep grades, which no ordinary locomotive can ascend. . . . Also of much larger transporting capacity than the unfortunate New York rapid transit system. The structure is very similar to the inclined plane system, but having stationary wheels for the continuously travelling ropes to rest on. The power is supplied by gearings at the ends, and the compressed air travelling to the various sections, enters a rotary fan drum, setting the large driving wheels with ropes in operation. The conductor grapples the rope to start, or releases his grapple to stop. It must be understood that the cars going down hill balance those coming up."

Mr. Hausknecht says in his letter that he predicted the failure of the Greenwich street plan, because "no engine can pull the rope with four-wheeled carriers when journals are overheated, because the wheels of said carriers were too many and too small for speed." This may be true, but this is not the reason why the system of endless ropes was abandoned in Greenwich street. Even if the road had been constructed after a method which Mr. Hausknecht may consider perfection it would have been the same thing; it is a fact that wherever the rope system has been adopted and retained circumstances were peculiarly favorable for the same, and the grade could not otherwise be overcome except at great cost and loss of time.

Mr. Hausknecht further says in his letter: "Does the editor know that endless rope systems for railroads have been in successful operation for many years by Elberfeld in Prussia, in Germany, France, Switzerland, Belgium, Pennsylvania, California, and even a short walk from New York, in Hoboken up Bergen Point, and of some 30°, about 482 feet high, carrying up cars, passengers, and horses safely on a platform truck."

To this the editor answers that he not only knows all this, but has travelled on most of the roads named, and many others besides. He went up and down the Elberfeld incline in 1847; it is not an endless rope, but the trains are attached to the ends of the same wire rope, the down train balancing the up train, while in many cases the stationary engine has little or no work to do, the locomotive of the two trains being often sufficient to move them. He has travelled on the famous Belgium incline, descending the valley of the Meuse near Liege; nor is there an endless rope here, the trains being hoisted up by a rope winding on huge drums, while the descending trains move by gravity alone and have their momentum regulated by a separate car attached to the rear and provided with special brake arrangements. It is the same with some inclines of lesser importance in France and Switzerland; in regard to Pennsylvania, the inclines which used to be in operation thirty years ago near Philadelphia, where the trains were hoisted up by stationary engines, have all been abandoned. It was the same near Albany, where the trains for Schenectady were hoisted up an incline to the summit of the table-land west of Albany; this also has been done away with and a gradual incline constructed, north of the city. The system has been retained for several inclines at and near Mauch Chunk on the Lehigh river; also for the ascent of the Moosic mountain near Carbondale, and near the Lackawanna river at Honesdale; and this for the simple reason that the trains on those roads are not drawn by locomotives at all, but move by gravity on a series of inclines. The topographical condition of the region being mountainous makes it easy to construct any kind of grades along the slopes of the mountains 1,000 and 2,000 feet high; but to recommend such a system in a city which is comparatively level, is absurd. The different inclined planes in Cincinnati ought to be mentioned in this connection; they are similar to that in Hoboken, but three times as high; nor is there an endless rope here, but the up truck balances the down truck, each being attached to the end of one wire rope, moved by a stationary engine on the top of the hill.

All these roads have been visited and studied by the editor, and he will only add that during a trip he made last summer over most all the railroads penetrating the interior of the Rocky Mountains in Colorado, he was struck with the ingenuity displayed by engineering the most difficult grades, ascending hights of 3,000 or 4,000 feet, without having recourse to ropes, endless or otherwise; not a single stationary train-hoisting engine was to be seen. Thus at Black Hawk the ascent is made by a series of switch-backs; and at the famous Veta Pass the road winds upward along the sides and around the mountains until Alamosa is reached, situated near the frontier of New Mexico, at the head-waters of the Colorado, about 10,000 feet high.

Experience has taught that the great problem of modern engineering is to avoid the very system recommended by Mr. Hausknecht, and for this reason we cannot comply with his request to publish his circular in full, so as to invite discussion. It has already been given more attention in our columns than perhaps the whole affair is worth, because it is a matter pretty well disposed of by all engineers who possess sufficient information on the subject, while we are perfectly satisfied that very few would have considered it worthy of as much notice as we have already given it.

Transmission of Power by Chains.

Of all the attempts to use chains for the transmission of power, the Ewart detachable drive chain has been the most successful. One form is represented in Fig. 1; there are many other forms, but we have not space to represent them here. They are all covered by pat-

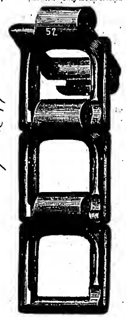

Fig. 1.

June 79

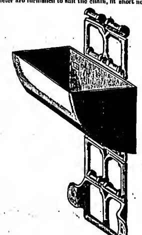
ents, which are owned by the Ewart Manufacturing Co., who manufacture them of the very best quality of malleable iron, and subject every link to inspection. The links are put together to make any length desired, and before shipping are tested in full lengths with a machine especially designed for the purpose.

The particular advantage claimed for this chain, is that it is not affected by the action of the weather, heat, cold, rain, chemicals, nor when running in water, as is the case with leather belting, which, under such circumstances, is soon destroyed. Another advantage is that it cannot slip, therefore it is of undoubted value in cases where positive and exact motion is necessary, and in vertical or inclined transmissions, and it may run so loosely on the wheels that a link may be readily taken out and replaced without removing the chain. It is largely used with malleable iron buckets in elevating phosphates, chemicals, and ores; for these uses it may be tinned or galvanized to prevent rust. It may be, and is, used on various machines, among which are harvesters, mowers, reapers, binders, headers, corn shellers, corn planters, windmills, middlings purifiers, threshers, cotton gins, governors, portable forges, pumps, water motors, drills, trimmers, live rolls, carriers and conveyors of all kinds; ice, grain, offal, shot, water, and tan-bark elevators; for traction engines, transmission of power in all classes of machinery, and in numerous other cases too numerous to mention, of which we will only describe a few, showing the importance of the application of Ewart's chain belt.

One is the straw carrier, of which a section is represented in Fig. 2; two chains, one at each side, are connected by cross bars, which move the straw forward on an upward inclined plane as rapidly as necessary, and pile it up beyond the most elevated end of the incline. Extensive farmers and dealers in fodder will at once see the advantage in cases where large quantities of straw have to be rapidly disposed of. Another application of far more importance is in saw mills, especially in regions where they are operated on a very extensive scale—for instance, in the timber regions of Michigan, Wisconsin, and Minnesota, we should say that the employment of this chain belt is indispensable. Besides securing the positive motion referred to, as well for the movement of the saw as for the carrying of the lumber while being worked; even for feeding light stuff to the saws feed chains are used to secure a regular parallel motion, and a smooth, even saw-cut. Then, for conveying the sawdust away, the chains are applied to elevator boxes. The dust coming from the saws, the finest parts of which are used for firing the steam boilers, passes through the grated floor on the lower chain, through which it is sifted; all the coarse pieces and bark that do not go through this sifting process are carried to the end and delivered into a receptacle, from which they are dumped into carts, while the fine sawdust sifted through falls on an inclined or perpendicular elevator, carrying it to an iron trough over the boiler; the trough is regularly fed by means of a V-shaped spout, provided with a slide to regulate the supply, according to the wants. These troughs are provided with a sheet-iron damper and counter-weight, so that when the chain, dragging through the trough, delivers sufficient dust into the spout to overbalance a counterpoise, the damper drops and delivers its load into the fire, closing again, so that the draft may not be obstructed by the slides or the top. The engineer, who regulates the supply, causes the surplus dust to be delivered outside; in this way firemen and shovellers are entirely dispensed with.

These sawdust carriers are made of wood, of such a size as to fit one large link of the chain; the best size is 2 feet wide over all, or 20 inches in the clear. The chain links and boxes are connected together by a screw-bolt and nut, as seen in the engraving. Lumbermen of the Northwest have not been tardy in endorsing these contrivances and introducing them extensively, and acknowledging their superior merits.

A large stock of links of different styles and sizes is carried by the manufacturers, and orders receive prompt attention. Wheels of nearly any desired diameter are furnished to suit the chain, at short notice.



Inquiries should be accompanied by a statement of speed desired to be run and purpose to which they are to be applied.

Mr. E. T. Copeland, of 30 Cortlandt street, New York, gives special attention to this article, and has applied it extensively as a substitute for belts and gearing. Through his agency it has found many new uses. Upon request sample links will be sent to any address, without charge or expense.

Facts Pertaining to the Manufacture and Uses of Wire and Wire Rope, and Telodynamic Transmission.

No. III.

THE transmission of power by endless belts of wire rope is one of the most important applications of such ropes in modern industry. It is often much more economical to transmit from its source the power required for manufacturing than to transport the raw materials to, and the manufactured products from such source. For example, a good water-power may exist on one side of a steep range of hills, while a railway or canal traverses the valley lying on the other side of the range. Now if the railway or canal be the channel through which the raw material to supply the manufactory must come, and through which the manufactured products must reach the market, it would probably be far cheaper to place the plant close to the railway or canal, and transmit the power from the source to the works than to carry the material and products to and from the factory.

Public attention was strongly directed to the method of transmission of power by wire rope at the Paris Exposition of 1867, where Mr. C. F. Hirn, of Mulhausen, Switzerland, exhibited a wire belt connecting a fifty-horse-power engine with a pump of great lifting power about a hundred yards distant. This exhibit, and the facts ascertained in relation to previous applications of the method of telodynamic transmission which were published in the report of the U. S. Commissioners, led to the adoption of the system in this country, where its employment is increasing. It has been found to be one of the most economical methods of transmitting power.

Instances were stated in the report above referred to of the transmission of power to points ranging from one to five miles from the prime motor.

Within certain practical limits the economy of the transmission will depend upon the following principles, which we find very clearly stated in the treatise quoted from in our former articles upon this subject:

"An mechanical power is measured by the product of *force* by the *velocity* with which it moves, so the one may be exchanged for the other, and a rope of one inch in diameter moving under a tension of 5000 pounds at the rate of 100 feet per minute conveys the same power only as one a quarter of an inch in diameter with a tension of 250 pounds moving at the rate of 2000 feet per minute.

"It is upon this principle that this system of transmission is based, viz.: *The transforming of power at its point of generation into velocity, and changing it back into force at its point of application.*"

Vertical grooved wheels of large size are used for the transmission at each end of the line. The grooves of the wheels are prepared with an elastic filling or packing upon which the rope runs, and which not only gives a good frictional bearing for the rope, but obstructs the wearing of the grooves. If the distance to which it is desired to carry the power be so great as to necessitate intermediate support for the belt between the transmitting pulleys, such support is supplied by intermediate pillars or piers carrying grooved idlers.

"A filling for the grooves now quite generally used and giving satisfactory results is made of sections of wood sawed from two-inch plank, the grain of the wood running lengthwise of the block; these are held in place by centre wedges, and when completely filled, the wheel is easily turned in place to a true circle. A small cushion of tarred rope is then run on the wheel for the wire ropes to track upon. This method of filling also protects the rope from wear upon the sides of the rim.

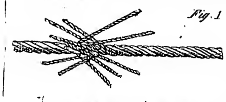


Fig. 1

"The wood may be of any of the tenacious varieties, of which hard maple is among the best. It should be well seasoned, and soaked in linseed-oil for about twenty-four hours before using, thereby rendering it weather-proof. This makes a much cheaper filling than rubber, and is one that can be '*home-made*' at any time.

"As the deflection of the rope is slight, any inequalities in the bearing surface of the wheels tend to produce vibrations of considerable amplitude, so in placing the rubber filling care should be taken that it be done uniformly.

"The wheels should also be well balanced, as from their great velocity they act also as balance-wheels, the evil effect of irregularities in which it is useless to comment on here.

"The arms of the wheels should be of such form as to offer the least atmospheric resistance, which, owing to their rapid motion, is considerable."

This resistance with improperly constructed wheels may equal the loss by friction. Mr. Haigh has paid much attention to this feature, and has at his works patterns of wheels of all sizes up to ten feet in diameter, so constructed as to reduce this source of loss to a minimum.

Fig 2

"The diameters of the wheels are measured from the outside of the filling, where the rope runs, and not from the edge of the rim. The hubs are made of sufficient dimensions to admit of boring to suit shafts of all sizes.

Care must be exercised in setting the wheels that they be in line, and that the shaft may be exactly at right angles with the line of transmission, that no vibrations from this source may occur."

As we remarked in a former article, Mr. Haigh manufactures by improved machinery wire rope of indefinite length without splicing. Nevertheless, in the use of wire rope some splicing can hardly be avoided. We therefore illustrate in the accompanying engravings the manner of procedure in making a splice, which with the description will enable any one of ordinary mechanical skill to perform the operation successfully:

"After having hauled the ropes taut and determined the length of one turn of the rope, by measuring along the rope the distance occupied by six strands; then,

"*First.* Unlay from each end a length of rope equal to about twenty-five times the length of one turn, remove the hemp centres and place the ropes so that their opposite strands will interlock each other, as in Fig. 1.

"*Secondly.* Unlay a strand from one end, and following the unlay closely, lay into the score or groove left by it the opposite strand on the other end, until all but a length equal to about three turns of the strand is laid in as in Fig. 2; then cut off the one unwound to a length equal to three turns, and tie them temporarily.

"*Thirdly.* Unlay a strand from the opposite

DISTRIBUTION OF WORK TO A DISTANCE BY ELECTRICITY. — Several experiments have lately been made in France in transmission of work by means of two Gramme machines, one made to produce electricity by mechanical work, the other to do the opposite and restore the work. Exact data of such an experiment at Sermaize (Marne) have been published by M. Tresca. There is a Gramme machine in the sugar works there, driven by a steam-engine at the rate of 1200 revolutions in a minute. This was connected by a copper wire or cable with a Gramme machine on a carriage at 400 metres distance, and another Gramme machine 250 metres further away; a commutator on the first carriage allowed of directing the current to work either machine as required. These secondary machines were caused to actuate drums with cables wound round them whereby ploughs of the double Brabant type were drawn a field. An effective force of 3 horse-power was thus obtained. The first Gramme actuated by the current made 1123 turns in the minute, the second 890. The current could also be applied to move the carriages on which the Gramme machines were conveyed.

June 78

PLOUGHING BY ELECTRICITY.—M. Tresca has succeeded in ploughing a field by electricity near Sermaize, in France. Three Gramme machines were employed; the first making 1,200 turns a minute, was driven by a steam engine of six horse-power. This current drove a second machine 400 metres off, at a speed of 1,120 turns per minute, or a third machine 980 metres distant, with a speed of 980 turns per minute, according as it was situated. The two last machines, which were portable, propelled two ploughs, which were of the Brabant type, by means of two cables. The available power in the process was estimated at three horse-power, showing a loss of 50 %.

June 78

Wire Rope Transportation at the Reading Iron Works.

At the Reading Iron Works a system of wire rope transportation is being built, which is expected to do away with much expensive handling and carting, and will offer a good example of a system which is rapidly gaining ground in Europe, and has been repeatedly used with success both in Eastern and Western States, although not to that large extent which its advantages warrant. At the Reading Works there will be three lines of transportation, the first of which will be 1,000 feet in length. It will be used exclusively for conveying pipes manufactured in the establishment to a siding along the Reading Railroad, 90 feet in length, where the pipes will be loaded upon cars. The second line will be 800 feet in length, and will be used for the transportation of Anthracite coal, while the third line will be 300 feet in length, and will carry soft coal and pea coal to the rolling mill. The trestles vary from 20 to 45 feet in height. The first line is supplied with two terminal and eight intermediate trestles, the second line with two terminal and four intermediate trestles, and the third line with two terminal and one intermediate trestle.

The main line will be equipped with an endless steel rope, 1¼ inches in diameter, which will run over sheaves or large wheels located upon the trestles, the rope fitting firmly into grooves in the circumference of each wheel. Grooved trucks will be fastened upon the chain, from which will be suspended hangers to support whatever articles may be transported. As this line will be used for carrying pipes almost exclusively, two trucks will be arranged in such a manner as to carry the pipes suspended upon the hangers. When the trucks reach the railroad siding they will be run from the endless rope upon the siding by an ingenious contrivance. From the center of the track to the center of the wheel, the gauge is the same as from the center of the rope to the center of the wheel. Upon the truck reaching the siding, the rope shoots at an angle, and the truck is run upon the railroad tracks with its freight. The moment the wheel strikes the rail the rope slips down and leaves the truck standing upon the rail. The truck is then disengaged from the rope and unloaded. While one line of loaded trucks is being conveyed from the pipe mill to the siding, a line of empty ones is being returned.

The operations of the other lines for carrying coal from the railroad sidings and dumping places to the pipe and rolling mills are of a similar character. The large sheaves or wheels, are 8 feet in diameter, and the small sheaves are 2 and 3 feet in diameter. The coal will be carried in buckets suspended from trucks fastened to chains. The power used in operating the endless ropes will be transmitted from a stationary engine by the line of shafting in the flue cutting department of the pipe mill.

The outlay for timber and labour would probably have reached £500 at most, and much of this would have been cheerfully defrayed by exhibitors. The authorities placing their trust in the weather and taking no precautions against contingencies, the success of the whole undertaking has been imperilled. Is it not true that, lavish as the Royal Agricultural Society is in some respects, it draws its purse strings the moment a demand is made for an addition to a permanent and hard-worked staff, even when such an addition is imperatively required?

Let us hope for the best, and suppose that the weather will be all that can be desired between this and Monday and all next week. Let us assume that every stand will be filled, every implement in its place, and consider for a moment what the visitor will see, and what the exhibition will teach most prominently. The implement shows of the Royal Agricultural Society are completely unparalleled. In no other country than England is to be seen year after year such collections of machinery and tools used in tilling the soil, reaping harvests, thrashing grain, and preparing food for man and beast. On the continent of Europe there are held now and then shows which follow at a great distance the example set by England. In America there are what is known as "State fairs," in which agricultural machinery figures prominently. But these things all sink into insignificance before such a collection as that to be seen at Kilburn. It will be impossible to walk through the yard without being convinced that agricultural engineers of Great Britain, alike in the ingenuity which they display, the skill which they possess, the capital which they employ, and the energy which they manifest in continuously endeavouring to improve on their past work, form a body absolutely unrivalled, and of which the nation may well be proud. There is not a quarter of the world to which they have not penetrated; there is not a region which they have reached and left unbenefitted. They have increased the food production of the world to an incalculable extent; and no man dare say that they have done all or nearly all that they can accomplish. To the progress of improvement there is apparently no limit; and that progress moves with gigantic strides is shown by the fact that forty years ago the portable engine was unknown, steam ploughing a thing of the future. What barn work was like may be gathered from an examination of the contents of the Museum, or even of the illustrations of some of its occupants which we publish. Even within the last twenty years enormous advances have been made. Who can say but that in the year 1919 a museum may be found in a showyard of the Royal Agricultural Society, in which much that we now regard as perfect will be looked upon by the visitors much in the same spirit that Cambridge's portable engine, Aveling's traction engine of 1860, Fowler's original steam plough, and the reaping and mowing machines of Hussey, Crosskill, and Burgess are regarded now. It has been said that all things are possible to him who waits. Agricultural engineers have proved that to them all things are possible, notwithstanding that their last thought is to wait.

June '79

TRANSMISSION OF POWER TO A DISTANCE.

ALTHOUGH it is now at least seventy-seven years since Bramah proposed to transmit power to great distances by means of water under pressure, and although it is half a century since Mann proposed and described the means for transmitting power over still greater distances by means of compressed air, it cannot be said that either of these means of transmission have been employed to the extent that their proposers expected they would be, nor to the extent to which they might profitably have been used in many countries. Telodynamic transmission has been employed to a considerable extent; but in several cases works erected for this purpose have been abandoned, as, for instance, at Belgarde. The loss of power in transmission by these methods is probably less by the telodynamic than by the others, but although M. Hirn, who has taken so prominent a part in bringing this method before the world, has upon reliable data calculated that this loss would be but about ten per cent. for distances not greater than twelve miles, there are sufficient reasons for saying that two or three miles is the greatest distance to which the system is practically applicable. One of the strongest objections to it is the great cost of the way works, while those which may be raised against the employment outdoors of great lengths of wire rope moving at high velocity are hardly less cogent. Hydrodynamic transmission comes perhaps next in order of economy, but this quality decreases rapidly as the power to be transmitted increases. For comparatively small powers the system is applicable, because only small quantities of water, but under high pressures, are sufficient. For large powers, however, the system loses its economy. Large mains are needed, and for the very high pressures necessary to economy the required strength of parts would involve great outlay; maintenance would be costly, and especially so where much of the machinery driven was of a reciprocating character and intermittently employed. As at present designed, moreover, the most economical hydraulic motors cannot be employed to work at high speeds; while the enormous strain to which such machinery is subject sets a limit to the size as well as the speed which may be practically attempted.

Pneumatic transmission really seems to offer greater advantages than either of the preceding. These were fully seen, and perhaps overrated at a time when experience in air compressing was very limited, and before the science of thermodynamics had acquired the shape in which it is now applicable to the uses of the engineer. It was not known that the loss of work in the form of heat during the process of compression and storage is sufficiently great to place a limit upon the application of compressed air as a transmitter, and that this loss would generally preclude its employment except in situations where the necessity for power is sufficiently

PLOUGHING BY ELECTRICITY.

The accompanying illustrations complete the article in our last issue on this subject. The carriage is of wrought iron, mounted on four iron wheels, the two side pieces being of I section. The two Gramme machines G G are mounted on a hinged frame connected to the side frames. These machines are connected at the upper part by means of a connecting-rod and a pair of india rubber rings (the friction wheel I and the spiral spring J not being found rigid enough were removed after the trial) which hold the pulleys on the end of the Gramme machine spindles against the pulleys D D. The small pulleys in the

rent pour les acides, on l'on trouvera le moyen de les produire à plus bas prix, et en aussi grande quantité.

Déjà MM. Solvay, nous dit-on, essayent un procédé qui reposerait sur la substitution de la magnésie à la chaux; dans la régénération de l'ammoniaque ils obtiendraient finalement un chlorure de magnésium au lieu de chlorure de calcium; ils y trouveraient cet avantage prétendu que le chlorure de magnésium est facilement décomposé, par la chaleur sous l'influence de la vapeur d'eau, en acide chlorhydrique et en magnésie. Je crains bien pour ces messieurs des déceptions sous ce rapport, car cette décomposition n'est ni aussi simple qu'elle en a l'air, ni aussi facile; les produits, en outre, peuvent laisser beaucoup à désirer. Assurément le problème n'est pas insoluble; espérons que MM. Solvay et Cᵉ auront encore la main heureuse et qu'ils arriveront des premiers, c'est ce que je leur souhaite dans leur intérêt comme dans celui de toute l'industrie.

USINES ET ATELIERS

TRANSMISSIONS PAR COURROIES ET PAR CABLES

(Comptes-rendus de la Société des Ingénieurs civils).

M. Leloutre donne communication de son Mémoire sur les transmissions par courroies et par câbles.

« Les recherches expérimentales que j'ai l'honneur d'exposer ont été commencées il y a une douzaine d'années au sujet de quelques travaux importants que j'ai été chargé d'exécuter; elles ont été complétées plus récemment pour établir des bases certaines pour la construction de transmissions par courroies et par cordes. »

Ce travail est partagé en quatre parties :

1°) *Recherches expérimentales sur l'allongement, l'élasticité et la résistance à la rupture des courroies en cuir et en caoutchouc, des sangles et des toiles.*

2°) *Recherches expérimentales sur le glissement des cordes et des courroies.*

3°) *Applications, et étude de transmissions exécutées. Analyse de quatre projets de transmission de 40, 80, 150 et 750 chevaux-vapeur.*

4°) *Renseignements pratiques et conclusions.*

§ I. — *Recherches expérimentales sur l'allongement, l'élasticité et la résistance à la rupture, des courroies en cuir et en caoutchouc, des sangles et des toiles.*

Au début de nos recherches sur les courroies de transmission je ne m'occupais que de la résistance à la rupture. Au bout de quelques essais, je m'aperçus que la détermination de la charge de rupture, des cuirs, des sangles ou des cordes n'est pas aussi simple qu'on veut le croire; puis l'allongement et l'élasticité m'ont révélé quelques faits intéressants.

En opérant sur des échantillons de cuir de même qualité on peut trouver des coefficients de rupture fort différents, selon le temps que l'on met à provoquer la rupture.

Pour mettre en évidence l'influence du facteur « *temps* » que l'on néglige si volontiers dans bien des travaux, j'ai dû prendre, en commençant mes recherches, quelques précautions, et fixer mon opinion sur quelques détails relatifs aux méthodes d'expériences que je comptais suivre.

Voici comment les opérations ont été conduites :

Dans une même courroie ou une même peau, j'ai fait découper une bande de cuir de 5 à 6 centimètres de largeur. Cette bande de cuir était découpée en trois ou quatre lanières réservées pour les expériences diverses auxquelles je comptais les soumettre. J'étais ainsi sûr d'avoir plusieurs échantillons de cuir de même qualité.

Ces lanières d'environ 700 à 800 millimètres de largeur furent munies à leurs extrémités de crochets en fer; l'un de ces crochets servit à les suspendre à un point fixe et, à l'autre, on appliquait des poids étalonnés que l'on augmentait graduellement jusqu'à la rupture; on relevait simultanément tous les faits intéressants sur l'allongement et l'élasticité.

Sur chacune des lanières on traça sur la partie supérieure un trait transversal très-fin, considéré comme origine pour la mesure des longueurs, sous les charges successives auxquelles on les soumettait; pour redresser les ondulations du cuir et pour tendre légèrement les lanières on les chargeait d'un poids de 2 kilogr. et au premier moment de l'application de cette charge on marquait rapidement un second trait, distant du premier de 500 m/m. Cette charge de 2 kilogr., augmentée du poids du crochet inférieur ou 2 kilogr. + c_r, nous l'appellerons *charge de tension*; puis on divisa l'intervalle compris entre ces deux traits en cinq parties égales de 100 millimètres.

Enfin on mesura la largeur et l'épaisseur des lanières en quatre ou cinq endroits différents, pour déterminer les sections transversales correspondantes. C'est le minimum de ces sections qui figure dans nos tableaux d'expérience. Ces dimensions ont été exprimées en 1/4 de millimètre, c'est-à-dire que les erreurs commises sont moindres que 1/8 de millimètre; on évitait dans toutes ces mesures l'emploi de compas d'épaisseurs, de calibres afin d'éviter les erreurs qui auraient pu résulter d'une compression possible du cuir; une discussion des erreurs probables nous permet d'affirmer que les résultats que nous discuterons sont approchés à moins de 2 %.

Ces dispositions prises, on soumettait les lanières à trois genres d'expériences :

1° Une des lanières fut soumise à des *charges rapidement croissantes* jusqu'à la rupture; pour commencer on ajouta à la charge de tension, 2 kilogr. + c_r, un poids de 5 kilogr.; au bout de cinq minutes on constata l'allongement, puis on ajouta encore 5 kilogr. à la première charge de 5 + (2 + c_r), et au premier moment de l'application de ce poids de 10 + (2 + c_r) on mesura l'allongement, puis encore celui qui se manifestait au bout de cinq minutes de cette charge, après quoi on augmentait le poids de 5 kilogr. et ainsi de suite jusqu'à la rupture; on

ELECTRO-TELEDYNAMICS.

BY PAGET HIGGS, LL.D., ASSOC. MEM. I.C.E.

(CONTINUED FROM PAGE 137).

Electrician Aug 14 1880

Some other points remain to be considered in the circuits employed for the transmission of power by electricity. One of these relates to the maximum heat effect, such as may be manifested in a calorimeter, obtainable on the exterior circuit, and representing the energy of the motor or driven machine. This maximum heat effect is obtained, as is well understood, when the resistance of the external circuit equals the internal resistance of the *effective* coils of the generator. When the resistances are so related, this maximum heat effect represents one-fourth of the work or energy of the generator. From this maximum the heat-work reclaimed can vary to ± zero, as the external resistance is varied 0 to ∞; and the total work will diminish, passing a value equal to half of the energy, or to the maximum efficiency of the work reclaimed, whilst the relative efficiency increases from 0 to 1.

When the electromotive force of the generating machine is not fixed, and under the condition that the mechanical power to be absorbed is the given quantity, the number of revolutions of the machine will increase as the total resistance (internal and external) is increased. Whilst the external resistance increases, the thermic efficiency will vary in absolute value from 0 to that of the work expended, the relative efficiency varying from 0 to 1.

When the electromotive force of the generator is a given quantity E, the work reclaimed on the second machine or motor during a unit of time is, at the maximum, represented by $c\frac{E^2}{4S}$, when $e = \frac{E}{2}$, and where c is the reduction constant. The expenditure of work will be variable, and $= c\frac{E^2}{2S}$; or the relative efficiency will be ½.

When the power applied to the generator is a fixed quantity, and the electromotive force is variable, thus varying E and e, the work reclaimed by the second machine or motor, $c\frac{V}{S}e$, will approximate more nearly to the work expended at the generator, $c\frac{V}{S}E$, in proportion as $\frac{e}{E}$ approximates to unity.

For the value of $\frac{e}{E}$, or the relative efficiency, constant, the ~~works expended and~~ reclaimed obviously increase in absolute value as does the value of $E-e$. But as the amount of mechanical work varies, so does the absolute value of the thermic work, and the limits of the values of E and e are those set for one consideration of modes of construction by the heat the insulating covering of the machines will support without burning, a kind of limit that has no practical value, since the efficiency of the machine is practically limited by the amount of current that the commutator of the machine will allow to pass without too speedy destruction. The quantity of current in webers $\left(\frac{V}{S}\right)$ determines a total thermic work of $c\frac{V^2}{S}$ calorics, of which the two machines take respectively $c\frac{V^2r}{S^2}$ calorics and $c\frac{V^2R}{S^2}$ calorics as motor and generator.

When the two machines are working at a relative efficiency of $\frac{e}{E}$, either should be capable of sustaining a velocity of armature, without heating beyond practical limits, that would produce in a wire circuit of the same resistance as the external circuit to be used in working, a thermic work $\left(\frac{1}{1-\frac{e}{E}}\right)^2$ times greater than the working limit set by the builder of the machine.

The engineer who has to transmit a certain amount of power a given distance will require to know how to select the machines best suited to his requirements; for he will, unless experienced as an electrician, scarcely adopt the alternative of constructing machines for his own use, if not prevented therefrom by patent rights and want of time. The first consideration will be that of the distance to be traversed by the connecting wire, which will require to be of as small diameter as may be consistent with the proper conduction of the current without loss by heating. This diameter and length will give the resistance ρ, which will again determine the best resistances R and r of the two machines (for more than two machines the best conditions have yet to be deduced). With $\frac{e}{E}$ given under the conditions of maximum in the preceding remarks, and with the value of V or $E-e$ deduced at sight from Ohm's law and the number of webers current required, all the data are complete, except those concerning the diameter and insulation of the line-wire. The determination of these last mentioned points is worthy to be separately considered.

TRANSPORT ÉLECTRIQUE

DU TRAVAIL MÉCANIQUE A DISTANCE

APPLICATIONS AU LABOURAGE, ETC., ETC.

SYSTÈME CHRÉTIEN ET FÉLIX

Le jour de l'Ascension, nous avons, en très-bonne compagnie scientifique, consacré nos loisirs fériés à entreprendre le petit voyage de Sermaize (Marne). Il s'agissait d'assister à des expériences de labour par l'électricité. Nous avons remarqué la présence de M. Tresca, membre de l'Institut et de la Société nationale d'agriculture, sous-directeur du Conservatoire des arts et métiers. La rencontre de M. Tresca est toujours de bon augure; il inspire aux inventeurs peu sérieux une considération mêlée d'une terreur justifiée par la raison qu'en mécanique cet éminent ingénieur connaît tout, mesure tout avec la compétence et la précision que l'on sait, sans qu'il soit possible de lui donner le change sur aucun point. Nous avons vu : M. Dureteste, inspecteur général des ponts et chaussées; M. Cabanellas; M. Begbeyder, ingénieur des mines; M. Galichet, ancien député, agriculteur; M. de Felcourt, président du Comice agricole de Vitry-le-Français, délégué de la Société des agriculteurs de France; M. Napoli, ingénieur chimiste et inspecteur au chemin de fer de l'Est, collaborateur de M. Marcel Deprez dans la construction des enregistreurs électriques de ce géomètre appliqués au wagon d'expériences dont M. l'ingénieur en chef Regray a doté la compagnie de l'Est; M. Richard, ingénieur des mines; M. Dumont, ingénieur; M. Hersent, entrepreneur des travaux publics; M. Tassin, etc. Le journal *la Lumière électrique*, le journal de l'*Agriculture*, le journal des *Travaux publics*, s'étaient fait représenter. Enfin, un grand nombre d'agriculteurs et de propriétaires de la région assistaient aux expériences. Quelques jours avant, M. Duphénieux, préfet de la Marne, et M. le général Clinchant, commandant en chef du 6e corps d'armée, étaient venus examiner avec intérêt les applications électriques de Sermaize.

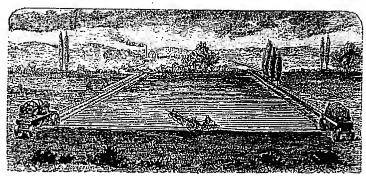
MM. Chrétien et Félix, ingénieurs très-avantageusement connus dans le monde industriel, ont, sans doute, comme cela est arrivé à bien des gens pratiques, arrêté leur pensée sur les conditions toutes spéciales qui caractérisent notre industrie du sucre : à une activité fiévreuse de quelques mois, succède, dans l'usine, une inaction absolue de tout le reste de l'année : il en résulte, qu'une puissance motrice toujours considérable, représentant un capital d'une grande valeur, se trouve immobilisée pendant tout ce temps, ce qui ne dispense pas d'un entretien minutieux et ce qui, à coup sûr, s'écarte beaucoup d'une bonne utilisation industrielle.

Il était donc d'autant plus logique de tenter la mise en culture du domaine par la force motrice de l'usine, qu'il est reconnu aujourd'hui, par la pratique de l'Angleterre, des États-Unis etc., même de l'Algérie, que la culture mécanique, partout où elle est possible, est économique, et augmente les récoltes dans la proportion d'au moins 30 p. 100.

19

Les labours mécaniques qui, jusqu'à présent, ont donné les meilleurs résultats comportent l'emploi de machines routières à vapeur actionnant des tambours sur lesquels s'enroule un câble d'acier qui remorque une charrue à socs multiples. Cependant ces appareils sont d'un prix élevé, leur conduite et leur entretien sont coûteux et exigent des soins spéciaux. Le poids est très-considérable et la manœuvre difficile dans les champs par temps de pluie; enfin, en dehors du combustible, le système nécessite un grand approvisionnement d'eau souvent fort incommode, et dispendieux au point qu'en réalité, les gens techniques estiment que cette eau arrive à coûter aussi cher que du charbon. Avec l'électricité, ces exigences disparaissent, les chariots complets pèsent environ deux tonnes au lieu de dix-huit, peuvent passer par tous les chemins, se manœuvrent avec une grande facilité, toujours à l'électricité; plus d'approvisionnement à transporter, ni charbon ni eau. On détermine la traction en tournant un simple conjoncteur métallique qui ferme le courant sur le moteur électrique; le sillon terminé, une autre touche de commutateur ouvre le circuit et envoie le courant au second chariot, rendant ainsi impossibles les avaries consécutives d'un malentendu non sans exemples qui a pour effet de mettre simultanément en action les deux locomobiles.

Les planches qui accompagnent cet article montrent clairement l'ensemble et les parties intéressantes du dispositif. Les données de l'expérience à laquelle nous avons assisté étaient les suivantes : deux machines Gramme ordinaires à lumière, dites du type A, étaient actionnées par le moteur de l'usine exportant leur électricité par un conducteur de cuivre de 3 m/m et faisant tourner, à 400 et 620 mètres de là, deux autres machines Gramme identiques. Ces machines, placées sur leur chariot respectif, aux deux extrémités du rectangle de



Labour électrique, vue d'ensemble.

terrain mis en labour et successivement animées par le courant, tiraient à elles, avec une vitesse de 40 à 50 mètres par minute, une charrue Brabant double, traçant des sillons larges de 30 centimètres et profonds de 20. La longueur des sillons était de 220 mètres, les deux chariots étant reliés par une longueur de 250 mètres de fil conducteur. En supposant la moyenne du travail du sillon d'aller égale à celle du sillon de retour, on peut regarder les travaux des machines comme proportionnels à l'inverse des temps, et, la durée du retour étant d'un cinquième moindre que celle d'aller, il en résulterait que le rendement en travail des machines Gramme, distantes électriquement de 650 mètres, serait les 80 p. 100 de celui des machines distantes de 400 mètres.

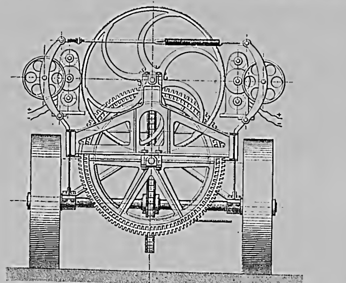
Avec les mêmes machines et du fil de 10 m/m carré de section, on a exporté le travail de l'usine à une distance de 2 kilomètres.

D'après les mesures dynamométriques prises par MM. Chrétien et Félix, tant à l'usine que sur le terrain, la moitié de la puissance empruntée à l'usine serait en moyenne transmise à la charrue, et nous avons estimé à environ trois chevaux de 75 kilogrammètres par seconde le travail moyen absorbé par le labour exécuté sous nos yeux. — Les ingénieurs de l'usine auraient trouvé plusieurs rendements supérieurs à 50 p. 100, mais il y a lieu de remarquer que les mesures dynamométriques étaient prises au frein de Prony, méthode qui procède par voie de substitution et ne comporte généralement pas une extrême précision. D'après les données théoriques actuellement admises (Travaux de MM. Mascart, Maxwell, etc.) et quelques expériences anglaises faites sur des machines Siemens, le rendement maximum ne peut dépasser 50 p. 100, rendement qui doit correspondre au point où la machine électro-motrice est animée d'une vitesse égale à la moitié de la vitesse de la machine électrique mécaniquement actionnée. Nous avons cependant des réserves à faire

20

sur ces points théoriques, nous les exposerons ultérieurement. D'ailleurs, pour le cas actuel, M. Tresca, rendant compte à la Société nationale d'agriculture de l'examen que cette Société l'avait prié de faire des applications de Sermaize, a dit qu'il allait expérimenter aux Arts et Métiers le rendement de ces machines Gramme du type A; nous allons donc bientôt être positivement fixés.

Quoi qu'il en soit, un rendement de 50, de 30, même de 25 p. 100, serait encore très-beau industriellement, si l'on réfléchit aux pertes énormes qui sont imposées par les transmissions usuelles et par la plupart des organes mécaniques avant d'arriver au travail effectif proprement dit qui est la raison d'être de ces organes. Il faut remarquer aussi que la force motrice prise à l'usine y est produite dans les conditions les plus économiques, par des machines fixes puissantes, qui peuvent facilement ne dépenser qu'un kilogramme de combustible par heure et par cheval, au lieu des consommations de locomobiles variables de 6 à 15 kilogrammes de houille. On réalise encore l'économie sur le personnel et l'économie de tout l'approvisionnement d'eau sur le terrain, dont il faut organiser et payer si cher le transport. Je ne parle pas de la mobilité absolue que le transport



Chariot électrique.

électrique du travail réalise d'emblée au point d'arrivée, quel qu'il soit.

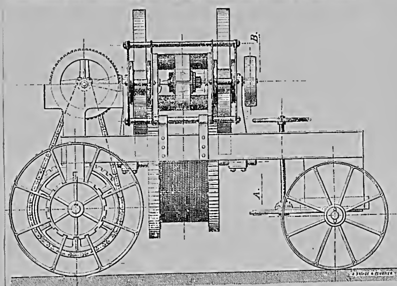
Les machines employées sont, comme nous l'avons dit, des machines usuelles à lumière, et il n'est pas douteux que des appareils spécialement combinés et construits ne soient appelés à se prêter beaucoup mieux encore à cet emploi.

On sait, en effet, que, dans les machines génératrices d'électricité par induction, le constructeur, par le seul changement des sections induites, est maître de la force électromotrice développée dans chacune des modifications relatives de positions de l'inducteur et de l'induit; la résistance intérieure se trouve alors modifiée dans le même sens, mais il en résulte néanmoins que la résistance extérieure non exploitée peut perdre beaucoup de son importance nuisible sur le travail extérieur utilement exploité, et nous ne doutons pas qu'il ne soit relativement facile d'établir de puissantes machines Gramme qui permettront l'utilisation d'un travail moteur à de très-grandes distances avec un bon rendement et en n'employant, comme circuit extérieur de transport de l'électricité que du fil métallique d'une section restreinte. Quand nous parlons d'une section relativement restreinte même avec les plus grandes portées qui pourront s'imposer dans l'application, nous ne risquons pas de causer de méprise, nous sommes seulement animé de cette conviction

21

que l'on doit tirer du principe tous les avantages qu'il comporte : car, dès aujourd'hui, avec les machines actuelles, on peut compenser par les dimensions du fil une augmentation quelconque de distance, puisque le conducteur extérieur n'a qu'un rôle passif en rapport avec sa conductibilité électrique effective, laquelle, en outre de la longueur, dépend de la conductibilité spécifique du métal et des dimensions transversales (section totale pour les circulations dites de quantité, et fonction analogue au périmètre extérieur total pour l'électricité de haute tension et certaines conditions de discontinuité dans la production).

MM. Chrétien et Félix ont combiné une série d'appareils mécaniques pour toutes les opérations de grande et moyenne culture exécutées en Angleterre au moyen de locomobiles : labourage, battage, hersage, sarclage, ensemencement. Ils ont établi des cabestans et des grues électriques d'un emploi très-commode. Ainsi, à Sermaize, pendant la fin de la dernière saison, une élinde, commandée électriquement de l'usine, prenait les betteraves dans les bateaux et les chargeait sur les wagons. Cet appareil a ainsi déchargé 4000 tonnes de matière première, réalisant, d'après le calcul du Directeur, une économie de 40 p. 100 sur la main-d'œuvre et permettant de s'affranchir d'un personnel spécial de débardeurs sur lequel on ne peut pas toujours compter.



Chariot électrique.

En résumé, nous qui ne sommes pas un converti des derniers jours, mais qui avons cru au transport du travail mécanique par l'électricité dès l'apparition des premières machines électriques réversibles, alors que ces machines étaient bien loin de l'état de perfection qu'elles ont atteint en dix ans, nous voyons avec une véritable satisfaction ces premières applications exécutées au grand jour, d'une façon pratique, sans complications inutiles, avec des dispositifs mécaniques assez bien entendus pour qu'il paraisse difficile d'admettre qu'on puisse les simplifier davantage.

Ces résultats font le plus grand honneur à MM. Chrétien et Félix, et les vastes horizons qui s'ouvrent ne leur ont pas échappé. Les applications peuvent être innombrables et d'une importance majeure.

Les économistes nous disent qu'il est urgent d'augmenter nos récoltes nationales et de diminuer les frais de mise en œuvre malgré l'insuffisance de plus en plus grande du travail manuel. Combien n'y a-t-il pas, en France et ailleurs, de puissances hydrauliques inutilisées faute de moyens économiques pour en transporter l'application à proximité des communications existantes?

La voie semble donc immense pour l'agriculture, et au même titre, pour un grand nombre d'industries.

GESSÉ.

Transmission of Power by Electricity.—Profs. Houston and Thomson have experimentally shown, at the Franklin Institute, that powerful electric currents can be conducted by very fine wires. They sent the current generated by one dynamo-electric machine through a wire .001 inch in diameter to a second machine, which, working reversely, gave off considerable power.

Ploughing by Electricity.—At a recent meeting of the Paris Academy of Sciences, M. Tresca gave an account of some experiments in ploughing by electricity which he witnessed at Sermaise, in the Marne. A Gramme machine, making 1200 revolutions per minute, and driven by a steam-engine, was connected to a second Gramme at a distance of 440 yards, and caused the latter to revolve at the rate of 1140 revolutions to the minute, the electricity produced by the first machine being thus converted into work. The second machine was connected to a third at a distance of 219 yards, and these two worked cables attached to a double Brabant plough. According to M. Tresca, the experiment was very successful, the work accomplished representing the equivalent of three horse-power, while one half of the motive power obtained from the steam-engine was really transferred to a distance of more than 1000 yards from the furnace.

LE LABOURAGE PAR L'ÉLECTRICITÉ

C'est déjà une expérience ancienne que celle qui consiste à réunir deux machines magnéto-électriques, à mettre en mouvement l'une de ces machines, pour produire un courant électrique et avec ce courant faire marcher en sens contraire l'autre machine, transformer ainsi un travail mécanique en électricité, puis, celle-ci transformée à son tour en travail mécanique. Le principe du transport de la force motrice à distance était trouvé; mais, jusqu'à présent, les éléments de précision manquaient, et, exception faite de quelques expériences entreprises par la Compagnie Paris-Lyon-Méditerranée, la distribution du travail à

distance au moyen de l'électricité était restée dans la limite restreinte d'essais de laboratoire et n'avait pas encore reçu une application vraiment pratique.

Aujourd'hui la transmission de la force motrice sur un long parcours, par un ingénieux emploi de l'électricité paraît être un fait acquis. Des expériences concluantes de labourage par l'électricité ont eu lieu le 23 mai à la sucrerie de Sermaize (Marne), et M. Tresca, membre de l'Institut, a bien voulu faire connaître le résultat heureux de ces expériences.

Voici dans quelles conditions les essais de labourage par l'électricité ont été dirigés.

Dans un des bâtiments de la sucrerie de Sermaize, un moteur à vapeur mettait en mouvement une machine magnéto-électrique de Gramme faisant 1.200 tours à la minute. Le courant développé était conduit par un fil de cuivre formé de neuf brins de 1 millimètre de diamètre, offrant ensemble une section de 7 millimètres carrés, à une distance de 400 mètres, sur un chariot où il pouvait d'ailleurs être dévié par un commutateur qui le dirigeait alors à 250 mètres plus loin, sur un autre chariot, en tout semblable au premier. Sur l'un ou l'autre de ces chariots et à volonté, le courant faisait fonctionner deux machines Gramme dont l'arbre entrait aussitôt en mouvement, et ce mouvement, convenablement ralenti par des organes intermédiaires, déterminait la rotation d'un tambour de 1 mètre de diamètre, sur lequel s'enroulait un petit câble de la grosseur de 12 millimètres, entraînant une de ces charrues dites *brabant* double, qui labourait ainsi un sillon de 220 mètres de longueur, à une profondeur de 18 centimètres, en moins de 5 minutes.

M. Tresca, à qui nous empruntons les détails qui précèdent, ajoute :

« La terre était résistante, et, bien qu'elle eût reçu un premier labour, qui l'avait ameublie, je ne pense pas que le même sillon, de 18 centimètres de profondeur, eût été produit, dans les appareils Fowler, avec moins de trois chevaux-vapeur. La résistance à la traction était la même dans les deux sens, et l'on peut déjà se rendre compte de la déperdition suivant la distance en remarquant que la vitesse du tirage, qui était de 0m,88 lorsque le fluide agissait sur le tambour du premier chariot, se trouvait réduite à 0,70 lorsque la longueur du circuit se trouvait augmentée, pour atteindre le second chariot, de deux fois 250 mètres. Au reste, l'arbre des machines Gramme actionnées par le courant, qui tournait à raison de onze cent vingt-trois tours par minute dans le premier cas, se réduisait à huit cent quatre-vingt-dix dans le second.

« Ces machines pouvaient respectivement déterminer, en outre, l'avancement même du chariot qui les portait, la disposition générale imitant en cela le procédé de labourage à vapeur dans le système à double machine routière, cheminant sur les bords opposés d'une pièce de terre. »

Quelle est exactement le rendement de ce mode de transmission de la force motrice?

Quelle est la relation entre le travail dépensé et le travail réellement produit?

Dans l'état actuel des expériences, il nous paraîtrait bien téméraire de présenter des chiffres, quels qu'ils soient.

Sans doute, la transformation de l'électricité en travail mécanique, problème souvent cherché et dont la solution peut avoir des conséquences et produire, comme le dit si justement notre éminent confrère, M. J.-A. Barral, une véritable révolution économique, est une idée féconde qui laisse le champ libre à toutes les conceptions et à toutes les espérances. Mais, avant d'affirmer que cette application nouvelle du fluide électrique peut rendre à l'agriculture et à l'industrie des services réellement pratiques, il faut attendre les essais nouveaux que M. Tresca doit faire dans bref délai au Conservatoire des arts et métiers.

E. Venelle.

Am. Machinist July 1879

(8) C. A., Brooklyn, N. Y., writes: I have heard a great deal about the transmission of power by wire rope, and I now write to you for information. I have a water wheel located in a mill which is now in use, and I also have a large building situated about 1,000 feet from the mill, which I would like to adapt to manufacturing purposes which will require power. What I wish to know is, if it is practicable to transmit power from the mill to the large building, and also if I could use wire rope as the means to transmit the power? A. It is practicable to transmit power by wire rope, not only the distance that you speak of, but a great deal farther, and is coming into use more every year. There is an instance in the neighborhood of Frankfort-on-the-Main, in Germany, where the power of 100 H.P. turbine is conveyed for a distance of 3,200 feet, by means of a rope transmission, to a cotton factory located in the proper place for such a building. Wheels, 13½ ft. diameter, making 114 revolutions per minute, are used; size of rope ⅝ of an inch diameter. There are eight intermediate stations or places where wheels are located at distances of 400 feet apart, it being found in practice that for any distance over 400 feet an intermediate wheel, or wheels, should be used—thereby making two sections, by which the speed is much more steady. In the above instance a nearer site for a building could not be found, and this was the only way that the power could be made available for that purpose.

Engineer July 18 1879

4686. TRANSMITTING ELECTRICITY TO GREAT DISTANCES, E. U. Pernot.—Dated 19th November, 1878. 8d.

This consists in the substitution for the telegraphic cables or wires of a condenser acting as a reservoir of electricity, and extending from one end of the territory to the other. This reservoir is charged at one of its extremities, or at any intermediate point between the extremities, by any suitable generator of electricity, actuated by any of the natural sources of motive power which abound in mountainous districts, such as rapids and waterfalls, and delivers the electricity with which it is charged at as many points as may be required along its whole length, for the purpose of supplying or actuating any machines or apparatus to which it is connected.

27

Eine neue Anwendung der Electricität.

Im Herbste des verflossenen Jahres hatte Herr Edison mit einem ihn besuchenden Reporter der "N. Y. Tribune" ein harmloses Gespräch gepflogen, in welchem auch von Transmission von Triebkraft mittels Electricität die Rede war. Nachdem sich die grosse Aufregung gelegt hatte, welche durch Edison's Behauptung entstanden war, ein electrisches Licht herzustellen, so theilbar und billig, dass es selbst das Gas im Haushalte verdränge, also zu einer Zeit, wo Mr. Edison die Ungeduld des Publicums, das Wunder von ihm erwartete, nicht sofort befriedigt hatte, da erschienen besonders in deutschen Blättern Kritiken über die Unterredungen, welche Edison mit den Berichterstattern über die Transmission von Triebkraft mittels Electricität gehalten hatte, die mit spitziger Feder geschrieben worden waren und die auch in technische Blätter England's übergingen.

Mr. Edison hat auf diese Angriffe mit seinem "lautsprechenden Telephon" geantwortet, und bezüglich seines Versprechens des electrischen Lichtes wird er auch sein Wort vollständig einlösen, nur muss man bei einer *solchen* Erfindung dem Erfinder Zeit lassen.

Was aber nun jene harmlose Besprechung der Transmission von Triebkraft mittels Electricität und jene durchaus verwerfende Kritik dieser Idee betrifft, *wer* hätte es wohl ahnen können, dass zwischen Diesen doch etwas praktisch Ausführbares und Nutzenschaffendes liegen könne? —

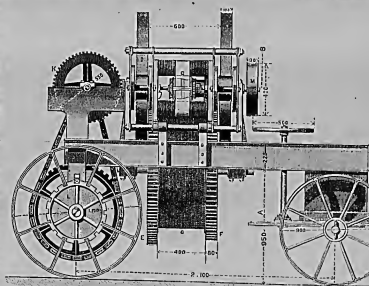
Und doch hat sich *solches* nunmehr herausgestellt, und zwei französische Ingenieure Namens Crétien und Félix überraschen uns mit der Anwendung von Triebkraft mittels electrischer Transmission zum — *Pflügen!* So hören wir, dass die Genannten vor Kurzem zu Sermaize, Departement Marne, Frankreich, mit einem von ihnen construirten Apparate gelungene Versuche mit einem neuen Systeme von Boden-Cultur angestellt haben.

Das Pflügen mittels mechanischer Kraft, wie es gegenwärtig in England, in Russland und in den Ver. Staaten vorkommt, ist von dem Gebrauche einer locomobilen Dampf-Maschine abhängig, welche neben dem zu pflügenden Lande aufgestellt ist und Trommeln in Gang setzt, über welche ein endloses stählernes Tau läuft, das dazu dient, den Pflug hin und her über das Feld zu ziehen. Diese Maschinen stehen aber in hohem Preise; sie sind theuer zu handhaben und zu unterhalten. Eigens muss man dabei darauf sehen, dass sie auch gut arbeiten, da sie in den Feldern oft eine abweichende Behandlung bedürfen, besonders bei regnerischem Wetter. Und schliesslich bedürfen sie auch noch eine beträchtliche Menge Wasser. Freilich ist die Arbeit, die durch sie verrichtet wird, auch besser gethan, und das tiefere Aufpflügen des Bodens, was nur durch mechanische Kraft vollbracht werden kann, steigert die Nahrungkraft der Oberfläche der Ackerkrume, so dass die Ernte um wenigstens 30 Prozent grösser wird.

Aber trotz all' dieser Vortheile hat das Dampfpflügen in Frankreich nur sehr wenig Eingang gefunden. Daran war die überwiegende Anzahl der Kleinbegüterten und die eben aufgezählten Kosten und Umständlichkeiten schuld, welche mit ihm verknüpft sind.

Zum Zwecke einer grösseren und allgemeineren Einführung mechanischer Kraft auf dem Lande haben nun die obengenannten Ingenieure ein Arrangement entworfen, bei welchem die Triebkraft von irgend einer festen Stellung aus angewendet werden kann, um die Arbeit auf mehreren angrenzenden Landgütern mittels Electricität, als Transmissionsagens einzuführen. Sie haben zu diesem Behufe die Gramme-dynamo-electrische Maschine zur Erzeugung der nöthigen Electricität adoptirt und ähnliche Maschinen als das electro-dynamische Mittel zur Wiederumwandlung der Electricität, die durch Kabel auf irgend eine beliebige Distanz fortgeleitet wird, in Triebkraft.

Zwei Formen solcher Maschinen sind bereits hergestellt und, wie schon oben erwähnt, durch Experimente erprobt. Eine derselben ist zum Entladen der Runkelrüben aus Booten, die andere zum Pflügen bestimmt.



Cretien & Felix's Elektrische Pflugemaschine. Fig. 1.

Die erstere stand den ganzen Winter über in Thätigkeit und ihre Anwendung stellte der Handarbeit gegenüber eine Ersparniss von 40 Prozent heraus. Abgesehen davon, dass die Rüben viel schneller entladen wurden (ein Ding von Wichtigkeit in der Rübenzucker-Fabrikation), so geschah dies auch ohne alle Beihilfe von Arbeitern, auf welche nicht immer ein sicherer Verlass besteht.

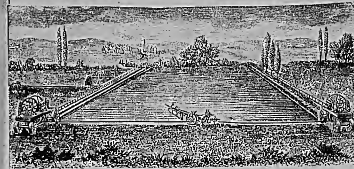
Letztere ist seit einiger Zeit auf einigen benachbarten Feldern im Betrieb und wurde mit balancirten Pflügen gepflügt, deren Haspelmaschinen wir illustriren.

Eine jede derselben besteht aus einem Wagengestelle von Schmiedeeisen, das auf vier eisernen Rädern ligt. Zwei Gramme-Maschinen, G G, stehen auf einem an die Seiten angemachten Ständer. Diese Maschinen sind an ihrem oberen Theile mittels einfacher Verbindungsstangen und ein paar Ruhberingen miteinander verbunden, welche die Riemenscheiben an den Enden der Spindeln der Gramme-Maschinen gegen die Riemenscheiben, D D, halten (das Arrangement von Reibungsscheiben, I, und der Spiralfeder, J, hat man nach gemachtem Versuche aufgeben müssen, weil es selbst bei geringer Friktion nicht hinlänglich Steifheit gab). Die kleinen Riemenscheiben in der Gramme-Maschinen sind mit Gutta Percha überzogen. Die Aufziehtrommel, C, erhält ihre Bewegung von den Riemenscheiben, D D, vermittels der Drehlinge, E oder F, welche je nach Bedarf langsamere oder schnellere Bewegung ertheilen. Auf dem Ende der Spindel, welche die Riemenscheiben, D-D, trägt, ist ein schräger Drehling befestigt, welcher in das conische Rad, K, eingreift, auf dessen Welle ein Treib-Drehling ist, über den und das Rad, L, eine Bandkette läuft, wodurch die Bewegung auf dem Seitenbande für den Haspel erlangt wird.

Das Steuern des letzteren wird vermittels eines Handrades, an der Vorderseite ersichtlich, gethan. Wenn nun die Maschine in Thätigkeit gesetzt werden soll, so werden die beiden Hinterräder vermittels einer Setzschraube, die dann wieder gelöst werden kann, auf ihrer Achse fest geschraubt. Das Seil, H, ist, wie schon oben gesagt, von Stahl, hat ½ Zoll Durchmesser und eine Länge von 1.3 Meilen, so wenigstens, wie man sich desselben zu Sermaize bedient. Die electrischen Cables werden an Pfosten, wie beim Telegraphen, fortgeleitet. Sie bestehen aus Drähten von 0.03 Zoll Durchmesser und geben eine sectionale Fläche von ungefähr 0.33 Zoll

Bei den vorgenommenen Experimenten wurden die Haspel in einer Entfernung von 664 Fuss aufgestellt und passirte der elektrische Strom vermittels Commutatoren abwechselungsweise das eine und dann das andere Paar von Maschinen, je nachdem der Pflug über das Feld hinüber und herüberging (siehe die beigegebene Abbildung). Eine Dampfmaschine, welche in der benachbarten Rübenzucker-Fabrik, ungefähr 1300 Fuss entfernt, aufgestellt war, setzte die dynamo-electrischen Maschinen, welche die Electricität lieferten, in Bewegung. Es waren etwa acht Pferdekraft nothwendig, um in leichtem Boden zwei Furchen auf einmal zu ziehen, welche jedoch in schwerem Boden nur für eine einzige Furche ausreichte. Die zum Pfluge transmittirte Kraft betrug drei bis vier Pferdekraft. Die Erfinder wollen jedoch eine Maschine herstellen, mit welcher sie im Stande sein werden, einen vierfurchigen Pflug zu benützen.

Die Gramme'schen Maschinen in der Fabrik hatten jede Minute 1600 Umdrehungen gemacht, an dem Haspel aber machten sie nur 800. Die Riemenscheiben, D, machten 133 Umdrehungen in der Minute und die Aufwindtrommel 14–27, je nachdem man sie langsamer oder schneller arbeiten liess, wobei die entsprechende Schnelligkeit des Pfluges 164–266 Fuss in der Minute betrug. Die Furchen waren 10.8 Zoll breit und 7.87 Zoll tief. Um zwei Furchen von ungefähr 24 Quadratyards herzustellen, bedurfte es nur Einer Minute. Ferner fand man aus, dass etwa 5 Prozent Arbeit der feststehenden Dampfmaschine auf das Feld übertragen wurde und dass die Wirksamkeit des electro-dynamischen Apparates von 30–60 Prozent je nach der Entfernung der Transmission betrug. Man nimmt an, dass diese Erfindung für Frankreich von grossem Nutzen werden wird, weil durch sie nicht nur viele Handarbeit erspart werden wird, sondern auch manche bisher unbenutzte Wasserkraft vortheilhaft (als Triebkraft für die Electricität erzeugenden Maschinen) verwendet werden kann.



Elektrische Pflügemaschine. Fig. 3.

Sc. Am. — Aug. 9 — 1879

TRANSMISSION OF POWER TO A DISTANCE.

ALTHOUGH it is now at least seventy-seven years since Bramah proposed to transmit power to great distances by means of water under pressure, and although it is half a century since Mann proposed and described the means for transmitting power over still greater distances by means of compressed air, it cannot be said that either of these means of transmission has been employed to the extent that their proposers expected they would be, nor to the extent to which they might profitably have been used in many countries. Telodynamic transmission has been employed to a considerable extent; but in several cases works erected for this purpose have been abandoned, as for instance at Belgarde. The loss of power in transmission by these methods is probably less by the telodynamic than by the others, but although M. Hirn, who has taken so prominent a part in bringing this method before the world, has upon reliable data calculated that this loss would be but about ten per cent. for distances not greater than twelve miles, there are sufficient reasons for saying that two or three miles is the greatest distance to which the system is practically applicable. One of the strongest objections to it is the great cost of the way works, while those which may be raised against the employment outdoors of great lengths of wire rope moving at high velocity are hardly less cogent. Hydrodynamic transmission comes perhaps next in order of economy, but this quality decreases rapidly as the power to be transmitted increases. For comparatively small powers the system is applicable, because only small quantities of water, but under high pressures, are sufficient. For large powers, however, the system loses its economy. Large mains are needed, and for the very high pressures necessary to economy, the required strength of parts would involve great outlay; maintenance would be costly, and especially so where much of the machinery driven was of a reciprocating character and intermittently employed. As at present designed, moreover, the most economical hydraulic motors cannot be employed to work at high speeds; while the enormous strain to which such machinery is subject sets a limit to the size as well as the speed which may be practically attempted.

Pneumatic transmission really seems to offer greater advantages than either of the preceding. These were fully seen and perhaps overrated at a time when experience in air compressing was very limited, and before the science of thermodynamics had acquired the shape in which it is now applicable to the uses of the engineer. It was not known that the loss of work in the form of heat during the process of compression and storage is sufficiently great to place a limit upon the application of compressed air as a transmitter, and that this loss would generally preclude its employment except in situations where the necessity for power is sufficiently urgent to make the question of cost of compressing power of minor importance. The latter objection, however, loses force when the compressing power can be obtained at little more than that of the necessary machinery for utilizing natural sources of power otherwise lost or wasted. A prominent illustration of this was the employment of air in the Mont Cenis tunnel, compressed by water power otherwise unused. In such a case as this, the great difference between the quantity of power expended in compressing the air, and that which can be realized by the best machinery worked by it, is of secondary importance, as the cost of the original power is nominal. In an article "On Water in Aid of Steam Power," in our impression for the 15th of October, 1875, we pointed out some of the places in our own islands whereat immense power is found concentrated at single spots, but which is wholly lost to man because it happens to exist at places where manufactures or industries cannot be advantageously established, though some of this power could be had for a mere nominal cost per horse. Much of this power, however, might be utilized if it could be transmitted to the places where it is required, and this transference, therefore, seems to be a question of sufficient importance to merit the careful consideration of engineers. In the article already referred to we showed that in Ireland alone there is running to the sea a quantity of water, the mechanically utilizable part of which would give 20,000 horse power at the lowest estimate. This enormous quantity of available energy is resident in five places, and for want of means of transmission to sites of employment, is wholly lost. There are many spots in Scotland, and a few in England, and very many abroad, where other large quantities of water pass on to the sea without being on their way made to act as the servants of man. Machines for compressing air, and that for reproducing the power which may be realized from that air transferred to a distance, have during the past few years been so much improved, that there seems sufficient reason to believe that such sources of power might be made to do duty in a variety of ways. The maximum distance to which air might be usefully transmitted would depend upon data not yet ascertained; but from what is already known, it seems that the loss of pressure [illegible] from 5 to 6 per cent. per mile for a distance of from four to seven miles. The number of centers of population which could be supplied with power from one place would therefore not be great.

In many cases, however, a considerable number of villages and perhaps several towns might be supplied with power sufficient to accomplish the work of water supply, sewage pumping, etc., and in some cases to perform work in factories. Particularly, however, we would draw attention to the large quantity of force which might be utilized for agricultural purposes within a comparatively short radius of any center of water power. The whole of the work of cultivation and food preparation, including thrashing and some harvesting, might be thus effected. The method of transmission remains to be selected. We have dwelt most upon the use of compressed air, which has now been sufficiently tried to make it pretty well certain that of every 100 horse power at a waterfall, from 40 to 45 might be realized at a farm at, say, from one to three miles distant. In some cases, however, difficulties would be met with in laying pipes for the transference of the air compressed at the waterfall. The power realizable by means of the fixed air motor at the farm might also in some cases be with difficulty transferred to the implements in distant fields. In view of these cases, it may be suggested that the apparent success in the fields at Sermaize of the electro dynamic apparatus, which we illustrated in our impression for the 13th of June, gives some indication that electricity may come to the aid of the farmer in transmitting power. It seems that at a distance of about a mile, the work realizable by the electro-dynamic machinery is from about 40 to 50 per cent. of that done upon the dynamo-electric machine, which in our case would be situated at the waterfall. At present the practical experience with this apparatus is perhaps not sufficient to justify any very definite statements as to its ultimate value, but enough is certainly known to make it fully evident that vast amounts of power, now wholly lost, might be made to do farm work. The electrical apparatus offers the great advantage of facility of transference, and the cable from the falls once laid or carried upon posts might remain in good order and without need of attention for years, and in this it offers advantages which might not always belong to transmission by compressed air in pipes. There are cases where the electrical transmission of power to fields might be found to be economical even when the electricity had to be generated by steam power. A really excellent fixed engine might be placed in the center of a farming district, and in a position to secure a good supply of water and the delivery of fuel at a minimum cost. This engine might work dynamo-electric machines and supply electricity within certain distances at a cost which would not greatly exceed the expense of steam power by ordinary farm engines, when the expenses of repairs and of carting water and fuel to these are taken into consideration. Power so transmitted might without doubt be made to replace horses for plowing with economy. The facility with which power may be transmitted by electric cables, and the ease with which it may be controlled, suggests that it should have a wide application in the ways we have suggested, and particularly it should be made the means of carrying the power of unutilized waterfalls to the fields and barns of the farmer.—*The Engineer.*

La transmission et la distribution de l'énergie au moyen du courant électrique

M. Lippmann vient de publier dans le bulletin de l'*Association scientifique de France*, une note très intéressante sur les recherches qu'a faites M. C. W. Siemens, sur la transmission et la distribution de l'énergie au moyen du courant électrique.

D'après cette note, M. C. W. Siemens aurait jaugé, pendant l'automne de 1876, le débit de la cataracte du Niagara; il a estimé la force de cette chute à 17 millions de chevaux-vapeur. Pour produire la même force par la vapeur, il faudrait brûler 260 millions de tonnes de charbon par an, quantité à peu près égale à la production annuelle de houille par toute la Terre.

Si l'on veut utiliser cette immense force perdue représentée par la chute du Niagara comme aussi par les chutes d'eau si nombreuses dans les pays de montagnes, il faut pouvoir en transmettre l'énergie à de grandes distances. L'électricité convient mieux à cet effet que l'eau ou l'air comprimé. On peut employer la chute d'eau à faire tourner une ou plusieurs machines dynamo-électriques et transmettre le courant produit à travers un conducteur métallique. M. C. W. Siemens, dans un discours adressé en mars 1877 à l'*Iron and steel Institute*, avait estimé qu'on pourrait, à l'aide d'une barre de cuivre de 3 pouces de diamètre, transmettre à la distance de 30 milles une quantité d'énergie égale à 1,000 chevaux-vapeur ou bien capable de produire une lumière de 250,000 bougies. L'auteur trouve aujourd'hui que ces chiffres sont beaucoup trop faibles : la force qu'on pourrait transmettre serait de 3,000 à 4,000 chevaux, et la quantité de lumière qui peut remplacer un cheval-vapeur est plus grande avec nos moyens actuels qu'elle ne l'était alors.

On distribuerait l'énergie du courant en établissant des dérivations sur le circuit principal. Afin de régler ces dérivations, M. C. W. Siemens propose d'employer des appareils dont il donne le dessin. Le courant dérivé traverse une tige d'acier qui s'échauffe et se dilate plus ou moins. Cette dilatation a pour effet de déboucher successivement les résistances d'un rhéostat métallique interposé dans le circuit dérivé. Dans un autre appareil, on utilise la propriété du charbon, découverte en 1856 par M. du Moncel et appliquée depuis par M. Edison, de fournir une résistance électrique variable avec la pression. Le courant dérivé parcourt une série de disques de charbon empilés, disques pressés les uns contre les autres avec une force réglée par la dilatation d'un conducteur échauffé par le courant.

La Correspondance Scientifique — 16 —

hroughout the matter without malice and as a journalist, believ-
ng that he was doing his duty. He would ask only a few further
questions of Mr. Croll, and then let the defendant stand com-
nitted for trial.

Mr. Croll said that the total cost of construction was £347,187,
and that included the discount on the £100,000 10 per cent. pre-
ference shares. Everything up to a certain period was charged
to capital account. The profit was about £16,000 a year, but he
could not tell whether in that account had been charged the
£4,000 a year for directors' fees.

The case was then adjourned until Friday for the depositions
to be copied, and the defendant was admitted to bail in his own
recognizances in £500.

AN ELECTRIC RAILWAY.

Some particulars respecting the electric railway which has been in opera-
tion at the Berlin Industrial Exhibition are given in the *Archiv fur Post
und Telegraphe*, from which it appears that this new exemplification of the
application of electricity as a motive-power sprang from a question ad-
dressed by Herr Westphal, a master builder of Cottbus, near Berlin, as to
the possibility of utilising the force generated by coal burnt at that village
by transmitting it to Berlin. The problem ultimately resolved itself into
the question how far electric force could be employed as a motive-power on
rails. The experiments which were instituted were successful, and led to
the construction of the electric railway, as it has been seen in operation in
the Berlin Exhibition. The arrangement is as follows:—There are two
lines of rails laid down, which, in a narrow-gauge line, return into them-
selves in a ring-shaped curve. The length is about 300 metres. In the
middle is an insulated third line, consisting of an upright, continuous iron
plate. The locomotive carries two rollers, with which it stands in connec-
tion with the insulated middle line. The essential portion of the locomotive
is formed by an electro-dynamical machine, one pole of which is connected
with the middle line and the other with the pair of outer rails, through the
outer wheels. Similarly the machine which produces the current stands in
the machine-room in connection through one pole with the middle line, and
through the other pole with the outer pair of rails. When, therefore, the
dynamical machine in the locomotive is on the railway, the electric current
produced in the machine soon runs through it and causes it to rotate and
to impart its rotatory motion to the wheels of the locomotive, and the latter
continues to move until the current is interrupted. Even an imperfect
state of insulation on the part of the rails does not materially affect the
action of the machine. When the locomotive is moving its conducting
wires form much better conductors than the damp earth. If the current
is interrupted, the damp ground is not a sufficient conductor to keep the
dynamo-electrical action going. The magnetism of the machines produc-
ing the current consequently disappears, and the result is that the subor-
dinate stream through the earth is also interrupted. A great advantage is
possessed by the transmission of electric force from the fact that the loco-
motive, whether moving slowly or quickly, always works up to its full
power—an effect which has hitherto been an unsolved problem in mechanics.
When the machine that gives the power has to do much work, and so goes
slowly, the counter-currents it produces are also correspondingly weak,
and the current through the conductors thereby undergoes an increase in
strength to a similar extent. By this means the electro-magnetism and,
corresponding to this, the attractive power of the machine are increased.
The dynamo-electric locomotive has the further advantage that it carries
in itself the power which can be employed as a brake, inasmuch as it be-
comes itself the primary or current-producing machine when it rotates
more rapidly than the actual machine. In judging of the performances of
the electro locomotive in the Berlin Exhibition it must be remembered that
it was not constructed for the purpose to which it has been applied—that
is, to propel the three elegant little passenger carriages which are attached
to it. Each carriage holds from 18 to 20 persons, and all three are drawn
in from one to two minutes round the circular railway of 300 metres in
length. The locomotive was originally made for the purpose of drawing
up coals out of a pit.

BRITISH ASSOCIATION.

ELECTRICITY AS A MOTIVE POWER.*

(CONTINUED FROM PAGE 192.)

Electric transmission of power then becomes not only practical, but very
economical both for short and for long distances, if we run both the
generator at the one end of the line, and the motor at the other end,
and if we only require to transmit a sufficiently large quantity of
power.

But this latter requirement is the essence of all successful trades, viz.,
that the per-centage of profits shall increase as the operations grow in
magnitude.

We have been considering the transport of power derived more especially
from natural sources; but since we have seen that by the use of electricity,
properly employed, the waste of power in transmission can be reduced for
any distance to about thirty per cent. of the whole power absorbed at the
generator, it follows that the employment of steam engines of vast size at
points outside Sheffield would be by far the most economical mode of
extracting the energy out of coal. For it is at least four times as expensive
to produce power with a small steam engine as with a large one; therefore,

* A Discourse delivered to the Working Men of Sheffield, August 23rd,
1879, by Prof. W. E. Ayrton.

Iron Aug 30 1879

Although Saturday is usually regarded as a *dies non* in the working department,
such was the abundance of important matter in the domain of physics, that some of
the sections sat for a while and did good work. For the most part, however, the day
was devoted to excursions and visits to works, which in all cases will be pleasantly
remembered from the courtesy and hospitality experienced in every direction. Of the
works visited we shall give an account next week, when we shall notice their special
features. On Saturday evening the Mayor of Sheffield gave a dinner to the members
of the Association, and which took place in the Cutlers' Hall, and at which about 350
gentlemen were present. On the same evening Professor Ayrton delivered a lecture in
the Albert Hall to working men, on "Electricity as a Source of Motive Power." In
his lecture, which we give *in extenso* on another page, Professor Ayrton showed that
electricity was a motive power, just as steam and water are, and predicted that at some
future time it would take the place of both these "old friends." The lecture was
illustrated by a large number of experiments, some of them being very startling
and brilliant. The platform and tables were covered with electric machines and
other scientific appliances, and a large number of diagrams had been specially
prepared and hung. To show that electricity could be used as a motive power,
though generated at a distance, a number of wires attached to machines on the
platform were connected with Messrs. Walker and Hall's works, in Howard Street,
some distance from the Hall, and the electric current was conveyed from the works
to the Hall. By this means a sewing machine was made to work, a small loco-
motive engine—which the lecturer called the "engine of the future"—was made to
perform a circular journey, a lathe was turned, at which a workman did some
turning; a circular saw was set in motion, and a quantity of wood sawn into thin
strips; spoons were plated, water was boiled, and the screw of a ship was turned.
Many other experiments were shown, and the conclusion the lecturer came to was
that electricity would some day become the great motive power of the world, and
would supersede gas for illuminating purposes. This lecture completed the enter-
tainments for the week.

Over

On Saturday evening Professor W. E. Ayrton delivered a lecture to working
men, which was crowded. The subject was "Electricity as a Motive-Power,"
and interesting illustrations were given, including machinery in motion, driven by power
derived from a distance.

Ayrton Aug 30 1879

The lecturer stated that in any generation of electricity there was a certain property called the
electro-motive force, which meant its tendency to send a current, and which was analogous with
the head of water in a reservoir, inasmuch as the product of the quantity of electricity flowing per
second, multiplied by this electro-motive force, measured the amount of energy furnished by the
generator per second, and which could be reproduced as motive power elsewhere if there were no
friction. The loss of energy due to electrical friction in the wires was equal to the square of the
current flowing per second multiplied by what was called the resistance of the wire—a number
depending on the length, the diameter of the wire, the material of which it was made, and the
temperature. The most efficient way to transfer energy electrically was to use a generator pro-
ducing a high electro-motive force, and a motor producing a return high electro-motive force, and
by so doing the waste of power in the transmission ought, he considered, to be able to be
diminished with the best existing dynamo-electric machines to about 30 per cent. It would be
impossible to increase indefinitely the speed of revolution of the cylinder of an induction machine,
since apart from mere mechanical friction the iron constituting the core of the revolving part had
to be magnetised and demagnetised very rapidly as it revolved. Now, there was a physical
limit to the speed with which this could be done, and in addition this rapid change of magnetism
heated the iron very much. But experiment showed that at the ordinary speed of revolution of
dynamo-electro machines—700 turns per minute—the electro-motive force was proportional
to the speed. They were, therefore, very far yet from the limit of speed. Consequently
it would be well for the transmission of power to attempt first, a considerable increase
of speed in the generator combined with so light a load on the motor, that its
speed would be also very high. When this began to fail as larger and larger amounts
of power were transmitted, then they might begin increasing the amount of wire on
the revolving coils of each; but this, of course, had the objection that the loss of power from a
given current would then become somewhat larger. As they had seen that by the use of electricity
properly employed, the waste of power in transmission could be reduced for any distance to about
30 per cent. of the whole power absorbed at the generator, it followed that the employment of
steam-engines of vast size at points outside Sheffield would be by far the most economical mode of
extracting the energy out of coal. For it was at least four times as expensive to produce power
with a small steam-engine as with a large one; therefore, including the waste of power in electric
transmission, the cost of production of power in small workshops would be little more than one-
third as dear as if small steam-engines were used, and similarly the waste of power in any large
mill or factory in its transmission from the large steam-engine at its base to all the floors and
machines on each floor would be very much diminished. But they would say that in advocating
the employment of electricity he was advocating a total change in our mode of producing and
transmitting power. Was the probable gain worth the expense of the necessary change? To
answer this question they must consider what would be the probable minimum annual gain by the
proposed change in Sheffield alone. In making this calculation they must remember that not only
could electricity produce motive power, but also heat and light, and electric heating and lighting
had this great advantage that no chimneys were required. For example, with the electric current
sent to that hall from Messrs. Walker and Hall's works he could heat a long coil of iron wire white
hot, so that when put into a vessel of water, the water in a short time would begin to boil.
Various calculations had been made as to the relative cost of lighting by burning coal to produce
gas, or by burning coal to work dynamo machines for producing electric currents, and it seemed to
be pretty certain that if a large amount of light be required in one place, that the electric light
was at least twenty times as cheap as coal; Sir William Thomson, the eminent electrician, went
so far as to say that it might be made 133 times as cheap. And certainly that there was a great
saving in expense in electric lighting was seen from the actual result obtained at the Albert Hall,
London, which was an example, and perhaps the only example in connection with electric lighting,
where the science of putting a brilliant light high up had been allowed to ride over the precedent
of putting a number of feeble glimmers all over a building. The actual cost, including labour of
men, allowance for wear and tear of machinery, &c., was only one-third of that of the former
inferior gas lights, and thus a saving of about 30s. an hour had been effected. Lighting streets by
electricity had not been so successful economically, for the simple reason that instead of giving a
large bright light, at a considerable height, reflected downwards, as in the Albert Hall, London,
English conservatism had prevented the authorities from grasping the possibility of using for street
illumination anything differing from an ordinary iron lamp post. But there could be little doubt
that if a few large electric lights, high up, were used for street illumination the same sort
of result as has been obtained at the Albert Hall would be arrived at. The cost
of using gas in Sheffield for lighting large halls, such as the one they were now
in, factories, and the streets, could be halved if electric currents generated by water-
engines, worked by hill streams, as well as by very large steam-engines, were substituted for
gas. It was not necessary for him to tell them how he proposed to employ the electric light to
illuminate private rooms, if only he could get people to throw away the notion that to light a
room they must have something with a globe on it, like an oil lamp; nor was it necessary for him
to remind them that by whitewashing the walls—yes, by whitewashing even the very machines
themselves—in some of the Paris factories, the supposed strong shadows cast by the electric light
had been less than the strong shadows cast by another bright light; one that we not only put up
with, but one that from the force of habit we were tolerably contented with, viz., the sun. At
present he was concerned with the pounds, shillings and pence question, which had more than
usual weight in these days of slack trade. Assuming that the cost of gas for lighting the large
buildings, factories, and the streets of Sheffield could be halved, also that where it was used for
heating purposes the expense could also be halved, by substituting electric currents generated by
very large steam-engines at certain points, and by turbines driven by falling water out of the town;
then they would save per year about £45,000. Supposing, also, that the cost of producing motive
power could in the same way also be halved, this represented an annual saving of something like

£60,000. In reality, he believed this last economy would be larger, since not only could power be produced so much more economically than by small steam-engines or even by a large engine, when a large proportion of its power was, as now, wasted in driving the shafting alone in their factories; but, in addition, much hand work could be economically replaced by machine work. And, lastly, supposing the consumption of coal in Sheffield for heating their metals and for heating their houses could also be halved, then there was another saving of about £300,000 a year; or, altogether, the annual saving that might be produced in this town alone, by substituting electricity for coal would be something like the large sum of £400,000. Last year, two French engineers, MM. Chretien and Felix, of Sermaize (Marne), actually ploughed fields by electricity, the electric current being produced by two dynamo-electric machines of a form invented by M. Gramme. These machines were usually worked with a steam-engine of some convenient place three or four hundred yards away in an adjoining road, and the electro-motors were also two Gramme machines, one on each side of the field, with their coils revolving of course backwards. Through one of these the electric current was sent alternately, so that motion was given to one or other of two large windlasses, one on each of the waggons containing the electro-motors. In this way the plough, which could be used going in either direction, was first pulled across the field making a furrow, and then back again, making another parallel furrow. If electricity were produced in large quantities at certain centres, then one difficulty that would of course be met with would be that of distributing it properly, since, just as in the case of water or gas, if a large branch pipe in a main be suddenly opened then the supply going on to the other branch pipes in the same main would be diminished, a result causing serious inconvenience in the case of electric lighting. But just as automatic governors had been devised for water and gas, to keep the supply constant, so automatic "electric current regulators" had been devised by M. Hospitalier and by Dr. Siemens, to keep the current constant. One of those invented by Dr. Siemens was on the table before him, and the general principle of its construction was easily understood. As the current passed through the regulator it heated a very thin ribbon of steel, which consequently expanded. The effect of this expansion was to introduce coils of wire into the circuit, the extra resistance of which diminished the strength of the current. Consequently the stronger the current the more was it automatically resisted, and the weaker it became the less was it resisted, and so it remained practically constant at any desired strength for which the regulator was previously adjusted. In conclusion the lecturer said there was a time when "Not only in the villages around old Sheffield," so said the historian of Hallamshire, "were the file makers' shops or the smithy to be seen, with the apprentices at work; but even on the hill side in the open country, at the end of the barn would be the cutler's shed, whilst in the valley below, by the river, was the grinding stone ready to sharpen the tools that had been manufactured." And why not now? Why should not that mountain air that had given the workmen of Hallamshire in past times their sinew, their independence, blow over their grindstone now? Why should not division of labour be carried to its end, and power brought to them instead of them to the power? Let them hope then that in the next century electricity might undo whatever harm steam during the last century might have done, and that the future workman of Sheffield would, instead of breathing the necessarily impure air of crowded factories, find himself again at the hill side, but with electric energy laid on at his command.

JOURNAL OF THE TELEGRAPH.

VOL. XII. NEW YORK, NOVEMBER 1, 1879. WHOLE NO. 288.

ELECTRICITY AS A MOTIVE POWER.

At a recent meeting of the British Association, Professor W. E. Ayrton delivered a lecture on "Electricity as a Motive Power," and interesting illustrations were given, including machinery in motion, driven by power derived from a distance.

The lecturer stated that in any generation of electricity there was a certain property called the electro-motive force, which meant its tendency to send a current, and which was analogous with the head of water in a reservoir, inasmuch as the product of the quantity of electricity flowing per second, multiplied by this electro-motive force, measured the amount of energy furnished by the generator per second, and which could be reproduced as a motive power elsewhere if there were no friction. The loss of energy due to electrical friction in the wires was equal to the square of the current flowing per second multiplied by what was called the resistance of the wire—a number depending on the length, the diameter of the wire, the material of which it was made, and the temperature. The most efficient way to transfer energy electrically was to use a generator producing a high electro-motive force, and a motor producing a return high electro-motive force, and by so doing the waste of power in the transmission ought, he considered, to be able to be diminished with the best existing dynamo-electric machines to about 30 per cent. It would be impossible to increase indefinitely the speed of revolution of the cylinder of an induction machine, since, apart from mere mechanical friction, the iron constituting the core of the revolving part had to be magnetized and demagnetized very rapidly as it revolved. Now, there was a physical limit to the speed with which this could be done, and, in addition, this rapid change of magnetism heated the iron very much. But experiment showed that at the ordinary speed of revolution of dynamo electro machines—700 turns per minute—the electro-motive force was proportional to the speed. They were, therefore, very far yet from the limit of speed. Consequently it would be well for the transmission of power to attempt first a considerable increase of speed in the generator combined with so light a load on the motor, that its speed would be also very high. When this began to fall as larger and larger amounts of power were transmitted, then they might begin increasing the amount of wire on the revolving coils of each; but this, of course, had the objection that the loss of power from a given current would then become somewhat larger. As they had seen that by the use of electricity properly employed the waste of power in transmission could be reduced for any distance to about thirty per cent. of the whole power absorbed at the generator, it followed that the employment of steam engines of vast size at points outside Sheffield would be by far the most economical mode of extracting the energy out of coal; for it was at least four times as expensive to produce power with a small steam engine as with a large one; therefore, including the waste of power in electric transmission, the cost of production of power in small workshops would be little more than one-third as dear as if small steam engines were used, and similarly the waste of power in any large mill or factory in its transmission from the large steam engine at its base to all the floors and machines on each floor would be very much diminished. But they would say that in advocating the employment of electricity he was advocating a total change in our mode of producing and transmitting power. Was the probable gain worth the expense of the necessary change? To answer this question they must consider what would be the probable minimum annual gain by the proposed change in Sheffield alone. In making this calculation they must remember that not only could electricity produce motive power, but also heat and light, and electric heating and lighting had this great advantage that no chimneys were required. For example, with the electric current sent to that hall from Messrs. Walker & Hall's works, he could heat a long coil of iron wire white hot, so that when put into a vessel of water, the water in a short time would begin to boil. Various calculations had been made as to the relative cost of lighting by burning coal to produce gas, or by burning coal to work dynamo machines for producing electric currents and it seemed to be pretty certain that if a large amount of light be required in one place, the electric light was at least twenty times as cheap as coal. Sir William Thomson, the eminent electrician, went so far as to say that it might be made 133 times as cheap. And certainly that there was a great saving in expense in electric lighting was seen from the actual result obtained at the Albert Hall, London, which was one example, and perhaps the only example, in connection with electric lighting, where the science of putting a brilliant light high up had been allowed to ride over the precedent of putting a number of feeble glimmers all over a building. The actual cost, including labor of men, allowance for wear and tear of machinery, etc., was only one third of that of the former inferior gas lights; and thus a saving of about 30s. an hour had been effected. Lighting streets by electricity had not been so successful economically, for the simple reason that instead of giving a large bright light, at a considerable heighth, reflected downwards, as in the Albert Hall, London, English conservatism had prevented the authorities from grasping the possibility of using for street illumination anything differing from an ordinary iron lamp-post. But there could be little doubt that if a few large electric lights, high up, were used for street illumination, the same sort of result as has been obtained at the Albert Hall would be arrived at. The cost of using gas in Sheffield for lighting large halls, such as the one they were in, factories, and the streets, could be halved if electric currents, generated by water engines, worked by hill streams, as well as by very large steam engines, were substituted for gas. It was not necessary for him to tell them how he proposed to employ the electric light to illuminate private rooms, if only he could get people to throw away the notion that to light a room they must have something with a globe on it, like an oil lamp; nor was it necessary for him to remind them that by whitewashing the walls—yes, by whitewashing even the very machines themselves—in some of the Paris factories, the supposed strong shadows cast by the electric light had been less than the strong shadows cast by another bright light, one that we not only put up with, but one that from the force of habit we were tolerably contented with, namely, the sun. At present he was concerned with the pounds, shillings, and pence question, which had more than usual weight in these days of slack trade. Assuming that the cost of gas for lighting the large buildings, factories, and the streets of Sheffield could be halved, also that where it was used for heating purposes the expense could also be halved by substituting electric currents generated by very large steam engines at certain points, and by turbines driven by falling water out of the town; they would save per year about £45,000. Supposing also that the cost of producing motive power could in the same way also be halved, this represented an annual saving of something like £60,000. In reality, he believed this last economy would be larger, since not only could power be produced so much more economically than by small steam engines, or even by a large engine, when a large proportion of its power was, as now, wasted in driving the shafting alone in their factories; but, in addition, much hand work could be economically replaced by machine work. And, lastly, supposing the consumption of coal in Sheffield for heating their metals and for heating their houses could also be halved, then there was another saving of about £300,000 a year; or, altogether, the annual saving that might be produced in this town alone, by substituting electricity for coal, would be something like the large sum of £40[illegible]000.

Last year, two French engineers, MM. Chreti[illegible] and Felix, at Sermaize (Marne), actually plowed fields by electricity, the electric current being produced by two dynamo-electric machines of a form invented by M. Gramme. These machines were usually worked with a steam engine at some convenient place three or four hundred yards away in an adjoining road, and the electro-motors were also [illegible] Gramme machines, one on each side of the field, with their coils revolving of course backwards. Through one of these the electric current was sent alternately, so that motion was given to one or other of two large windlasses, one on each of the wagons containing the electro-motors. In this way the plow, which could be used going in either direction, was first pulled across the field, making a furrow, and then back again, making another parallel furrow. If electricity were produced in large quantities at certain centres, then one difficulty that would of course be met with would be that of distributing

THE ENGINEER.

FEBRUARY 6, 1880.

ELECTRICITY A FORM OF FORCE.

This was the main text of Mr. W. H. Preece's inaugural address to the Society of Telegraph Engineers, which we briefly noticed in our last number as having been delivered. If Mr. Preece had deliberately selected a subject for his presidential address that should best serve as a "bone of contention," he could not have chosen a better topic. We should not be surprised to learn that, seeing the dearth of controversy existing at the present moment, the happy inspiration flashed through his mind to give an inaugural address containing the greatest possible number of ideas directly antagonistic to received teaching. The language in which the address is couched is a good example of our best and most lucid scientific exposition. There is no mistaking the meaning; no mere verbiage hides the conclusion which is deduced; there it stands clear and distinct. But the question will arise—Are these conclusions real, or are they put forward as a means to an end? If Mr. Preece has used them to serve a purpose, he will of course gain from the work of the critics labouring to demolish his airy structure. Although we may infer from internal evidence that the author is joking, we must, until better informed, take the statements of the president of a learned society as *bona fide* expressions of his deliberate opinion. It is not our intention to discuss the questions touched upon in the address *seriatim*, though the whole teems with controversial matter. Mr. Preece was careful, and we think wisely so, to introduce his conclusions as resting entirely "on the imaginative power of the mind." Prof. Tyndall has much to answer for, but we doubt if he would not prefer his disciples to test the results of the imagination by experiment when possible, or at all events to make sure that such results are logical.

"My purpose," says Mr. Preece, "is to contend that electricity is not a form of matter, but a form of force, and that all its effects are evident to us in one or other of the several forms of energy characterised by the motion of molecules or of mass." An argument brought forward in support of this contention is "that when a wire conveys a current of electricity it is warmed, as the strength of the current is increased it is heated, and eventually rendered incandescent. The ultimate form which every electric current takes is heat. The wire of every telegraph is warmed in proportion to the currents it transmits. Joule showed that when this heat is produced by a current generated in a battery by chemical force, its amount, is exactly equivalent to that which would have been evolved by the direct combination of the atoms. The conducting power of all bodies is affected by heat, and some even, like selenium, by light. Hence, as we know that in the case of heat and light conduction is molecular vibration, we reasonably conclude that it is the same with electricity." The test of every theory is, according to the author himself, that it "must agree with every observed fact." How does this assumption relating to the heated wire agree with fact? In order to have an electric current we must have an electric circuit, and no matter at what part of the circuit a galvanometer is inserted, the needle gives the same deflection under the same conditions. If in the circuit we have an incandescent wire, the galvanometrical deflection on both sides of the wire is the same. Now, between these two points there is the glowing wire. Something causes the heat, and the question remains what is this something? The quantity of electricity passing on the one side is the same as on the other. Clearly then, Mr. Preece's form of force being the same on the one side as the other, produces light without any loss. This means the possibility of perpetual motion. There is no doubt about the fact. Two voltameters, one on either side of the incandescent wire, show equal volumes of water decomposed in equal times. According to this theory, however, we use our mode of force, and keep it too. The explanation generally given as to what causes the incandescence is extremely simple, it is a pity that it should be found to diverge so far from experimental facts. We do not deny, argue the supporters of the theory, that the current is the same in all parts of the circuit, but the current is much smaller after the insertion of the wire that becomes incandescent, than it was previous to such insertion, and the difference between the two currents is the electricity used to give the light. This argument really makes matters worse, inasmuch as now the theorists pretend to use a current which never exists. The difference between the observed currents is not due to the cause above mentioned. When the wire to become incandescent is brought into the circuit, there is, so to speak, a retardation in the production of the current. The introduction of this new resistance diminishes the quantity of current in a given time, and surely that which does not exist cannot give us light. We shall try and make this quite clear, for it is owing to the ignorance of these fundamental and experimental truths that so much nonsense is written and spoken. Suppose we have a powerful battery, the terminals of which are connected through two voltameters, or galvanometers by means of copper wire. The current will decompose a certain amount of water in each voltameter in a given time, or deflect the galvanometer needle so many degrees. After the action has continued, say, an hour, weigh the zincs of the battery—having carefully noted the weight at the commencement of the experiment—we find the loss of weight to be, say, 1 lb. Now, insert at some point between the galvanometers a piece of platinum wire, the needles immediately drop several degrees, and we get a brilliant light. At the expiration of an hour, weigh the zincs again, and it will be found that less than 1 lb. has been consumed. In other words, the lessened needle deflection was caused by the lessened production, and not by the consumption of the current to produce light.

We come to a point in this address where it seems that boldness has given place to rashness, or the statements of the late Clerk-Maxwell would hardly have been criticised. The late Professor was a giant, against whom it was dangerous to contend; and his carefully studied conclusions require much stronger evidence than has been advanced by Mr. Preece before they will be overthrown. The latter states:—"Clerk-Maxwell, in his classical work on electricity, has used a somewhat curious argument to show that electricity is not, like heat, a form of energy. He says that energy is produced by the multiplication of 'electricity' and 'potential,' and that it is impossible that electricity and energy should be quantities of the same category; for 'electricity' is only one of the factors of energy, the other factor being 'potential.' But," says Mr. Preece, "this does not militate in any way against the force of the argument, for in nature we can no more do so (*sic*) than we can separate heat and temperature. Energy usually appears as the product of two factors, and it is the equivalent of the work done. Thus potential energy is the product of mass and gravitation acting through a distance. Kinetic energy is the product of mass and the half-square of velocity. . . . The energy of heat is made up of heat and temperature, and the energy of electricity is the product of electricity and potential. Hence it is that electricity, *per se*, may be said to be a form of force, while all its effects, as known to us, are forms of energy. Force alone cannot produce energy; it must be force and something else. Force is the power of producing energy, and it must have something on which to produce it. Hence, matter is always present; and thus though heat, light, and electricity are forms of motion, they are in reality properties of matter from which they are inseparable. They are evident to us through the play of molecules of matter, and thus are properly called molecular forces." Now, although there is no lack of material for criticism here, we prefer to call attention to a statement of Clerk-Maxwell, forming part of the text to that commented on by Mr. Preece. "We have proved that "it—electricity—cannot be created or annihilated, so that if the total quantity of electricity within a closed surface is increased or diminished, the increase or diminution must have passed in or out through the closed surface." This is true of matter; it is not true of heat—it is not true of energy if we admit the immediate action of bodies at a distance. It will be seen from this that Mr. Preece has used his analogies only so far as they seemed to fit his theory. To return to the above extract, it would seem that Clerk-Maxwell and Mr. Preece must be talking about two different things. May we not follow the plan proposed by Mr. Preece, and see the result to which an imaginative mind will lead us? Taking for our example the incandescent wire in the circuit, as previously explained, we can imagine electricity plus something in a high state of activity at the one pole of the battery, whilst at the other pole we have the same quantity of electricity without the something additional. In other words, this active component of electrical energy has been lost during its passage through the wire. This component which has thus been lost is generally termed potential. Electricity is there, but potential is gone. Reasoning analogically, the action is somewhat similar to that of water going from a higher to a lower level, and during its passage turning the wheel of a water-mill. The same quantity of water passes on the one side of the mill-wheel as on the other, no water has been lost, but yet work has been done. The similarity between the action of water and the action of electricity in these cases is so marked that it leads us to say electricity is not a force, but something carrying a force.

We do not say that electricity is not a mode of motion, but we do say, and that most emphatically, that neither Mr. Preece nor any other electrician has as yet proved electricity to be a mode of motion. It seems to us that a similar process of reasoning will enable us as satisfactorily to show that electricity is not a "form of force" and that it is a "form of matter."

Kent's Autographic Transmitting Dynamometer.

Am. Machinist

The accompanying engraving represents a dynamometer used at the Stevens' Institute at Hoboken, during the recent experiments with machines for producing electric lights. These experiments with their results have been published in a government report of the Light House Board, by Prof. Henry Morton, from which we print the following extract:

The power employed in driving the machine was taken by the use of a transmitting dynamometer, designed by Mr. William Kent, a graduate of the Institute, and built in the workshops of the Institute by the graduating class of 1879. This is in fact a modification of the dynamometer invented by Mr. Samuel Batchelder, of Boston, nearly forty years ago. The modification consists in providing a method of making an automatic record, and of indicating more minute variations of the power transmitted. The accompanying cut represents the dynamometer without the recording attachment, and as it was used in the experiments. The construction of this apparatus and its mode of operation are as follows:

It consists, as shown, of two stout cast-iron frames, held together by bolts in bearings, in the top of which frames run two shafts, each carrying a pulley at its outer end and a bevel-gear wheel of 45° at its inner end. One of these shafts is the driving-shaft, connected by belt to the engine or other prime mover; the other is the driven shaft, connected by belt to the machine driven. The power is transmitted from one shaft to the other through two other bevel-wheels of 45° gearing with the first, the shaft common to them and on which they run freely being at right angles to the axis of the two shafts first mentioned and carrying at one extremity a heavy pendulum.

The bevel-wheels being connected, as shown, and the power being applied to the driving-wheel, the two intermediate wheels with their common shaft have a tendency to revolve around the driving-axis, which tendency is a measure of the force transmitted, and is resisted by the moment of the weight of the pendulum. In the Batchelder dynamometer the four bevel-wheels and their shafts are used, but the shaft connecting the intermediate wheels is always held in a horizontal position, and its tendency to revolve is resisted by weights and a sliding poise applied to an extension of one end of it, which is graduated like a scale-beam. In using the Batchelder dynamometer the operator requires to keep the beam constantly balanced, by shifting the poise on the scale-beam or the weights in the scale-pan hung at its outer end, to correspond with the variations of the power transmitted, and a record of the power is obtained by noting the weight on the scale-beam at each instant, and the corresponding number of revolutions of the driving-shaft. The horse-power is obtained by multiplying weight in pounds of weighting poise on the scale-beam by the distance in feet of its point of suspension from the driving axes, by the number of revolutions per minute, by 3.1416, and dividing by 33,000.

In the improved dynamometer the horizontal scale-beam with its weights and sliding poise has been dispensed with, and the swinging pendulum substituted. The tendency of the shaft carrying the two intermediate bevel-wheels, the prolongation of which shaft is the pendulum arm, to revolve around the driving-axis, is measured by the weight of the pendulum and its arm multiplied by the distance of their center of gravity from the driving-axis and by the sine of the angle which the pendulum arm makes with the vertical. When the pendulum hangs in a vertical position the force transmitted is zero, errors due to friction excepted, and when it is horizontal, the sine of the angle being equal to unity, the force is the maximum the apparatus is capable of recording. The weight of pendulum and its position on the arm being constant, the only variables to be considered in measuring the horse-power transmitted are the number of revolutions per minute and the sine of the angle of the inclination of the arm. These variables may be caused to automatically record themselves on a sheet of cross section paper by any one of a number of devices.

The dynamometer used in these experiments has a capacity for measuring 20 horse-power; a method is provided of measuring very small powers, which consists in lessening the moment of the pendulum and arm; first by shifting the sliding weight nearer the driving-axis; second, if still lighter moment is desired, by removing the weight from the arm entirely; or, third, if even still greater delicacy is desired, by counterbalancing the weight of the arm by adding weight to its upper end, above the upper intermediate bevel-wheel.

During the experiments one person attended to the running of the engine, dynamometer, and machine, while another recorded the number of revolutions of the dynamometer and the inclination of the weighted pendulum; the latter was read from a graduated arc fastened to the pendulum in such a manner as to lie in the same plane with its axis; this arc, by the deflection of the pendulum, swung by a pointer attached to a cross-belt at back of machine, and thus indicated the degrees of inclination of the pendulum. The friction of the dynamometer was obtained by loading its delivery shaft with a weight which produced the same pressure on the bearings as was brought on them when it was transmitting power to the light machines, and then noting the deflection of the pendulum to overcome the friction produced.

In the earlier experiments the readings of the dynamometer were recorded every fifteen minutes, and in the later ones every five minutes.

Photometric measurements were also made simultaneously with the reading of the dynamometer, and occasionally one or two between successive readings of the dynamometer.

THE SOCIETY OF TELEGRAPH ENGINEERS.

THURSDAY, JUNE 3, 1880.

THE DYNAMO-ELECTRIC CURRENT IN ITS APPLICATION TO METALLURGY, TO HORTICULTURE, AND TO THE TRANSMISSION OF POWER.

Electrician June 12 1880

By Dr. C. W. Siemens, D.C.L., LL.D., F.R.S.

Dr. Siemens commenced by referring to his inaugural address in 1878, in which he called attention to the use of electricity in transmitting power and in electro-metallurgy. He then proceeded to describe three somewhat novel applications of the dynamo-electric machine, viz., as a means of effecting the fusion of refractory materials in considerable quantities in an electric furnace; in certain effects in horticulture; and as a means of mechanical propulsion.

The paper was rendered the more interesting as experimental results were shown, as well as described and illustrated by diagrams.

Dr. Siemens showed that the electric arc is not only capable of producing very intense degrees of heat in a focus or extremely contracted space, but also such larger effects of intense heat, with moderate expenditure of energy, as will render it useful for effecting the fusion of platinum, iridium, steel, or iron, or for such reactions or decompositions as require for their accomplishment an intense degree of heat, coupled with freedom from disturbing influences such as are inseparable from a furnace worked by the combustion of carbonaceous material.

Dr. Siemens exhibited his furnace, and demonstrated its utility by melting steel. The apparatus employed to effect this electro-fusion consisted of an ordinary crucible of plumbago, placed in a metallic casing, the intervening space being filled up with some bad conductor of heat. A hole is pierced through the bottom of the crucible for the admission of the conductor connected to the positive pole. The cover of the crucible is also pierced to receive the negative pole. The negative pole is connected by a strip of copper to one end of the beam of a balance, the other end being attached to a hollow cylinder of iron, free to move vertically within a solenoid coil of wire. By means of a sliding weight the balance can be adjusted, to balance the magnetic force with which the hollow iron cylinder is drawn into the coil. The variation in the resistance of the arc is counteracted by the action of the solenoid. This automatic adjustment of the arc is of great importance to the attainment of advantageous results in the process of electric fusion. Without it the resistance of the arc would rapidly diminish, and heat would be developed in the dynamo-machine to the prejudice of the furnace. The sudden sinking or change in electrical resistance of the material undergoing fusion would, on the other hand, cause sudden increase in the resistance of the arc, with a probability of its extinction, if the automatic action were wanting. It is important that the material to be fused should constitute the positive pole of the battery. Here heat is principally developed, and fusion takes place before the crucible itself is heated to so high a temperature. Dr. Siemens gave some interesting quantitative explanations. He said the dynamo-electric machine, consuming 4·25 horse-power, or 3·17 ergteus per second, will send a current of 40·5 webers through 1 unit electrical resistance; replacing the resistance by an arc maintained by the balance-weight constantly at 37·8 volts electromotive force, the same current will flow.

Neglecting the connecting wires, there will be developed in the arc an energy of

$$1{,}531 \cdot 2 \times 10^7 \text{ ergs. per second} =$$
$$9{,}187 \cdot 2 \times 10^8 \text{ ergs. per minute} =$$
$$1{,}378 \cdot 1 \times 10^{10} \text{ ergs. per 15 minutes} =$$
$$32 \cdot 8 + 10^4 \text{ gram water degree units of heat.}$$

Assuming steel to have the same specific heat as iron, viz., at 1° =

$$\cdot 1010 \times 0 \cdot 0001 4 4,$$

and that the melting point of steel is 1800° C., then 420·5 units of heat will be expended in raising the steel to this temperature; and assuming the latent heat of fusion at 29·5 units (silver is 21, and zinc 28), there are roughly 450 units required to melt a gram of steel, and 225,000 to melt half a kilogram, that is about $\frac{2}{3}$ of the heat generated in the crucible, and $\frac{1}{3}$ of the horse-power actually expended. A good expansive condensing steam engine converts the heat energy residing in coal into mechanical energy, with a loss of about eighty per cent., or, in other words, $\frac{1}{5}$ only of the 7,000 units residing in a gram of ordinary coal is represented as work in the engine. The useful effect attainable in the electric furnace is therefore $\frac{1}{3} \times \frac{1}{5} = \frac{1}{15}$ of the heat energy residing in the fuel consumed under the boiler of the engine.

To melt a gram of steel in the electric furnace takes, therefore, $450 + 15 = 6{,}750$ units, which is within a fraction the heat energy residing within a gram of ordinary coal. It results from this calculation that, by means of the dynamo-electric machine worked by a steam engine, one pound of coal is capable of melting one pound of mild steel. In melting steel in the ordinary air furnace, as practised at Sheffield, three tons of best Durham coke are consumed to melt a ton of mild steel in crucibles, and in working with the regenerative gas furnace, one ton of coal effects the fusion of one ton of steel in crucibles, whilst to produce steel in large masses on the open hearth of this furnace, 12 cwts. of coal suffice to produce one ton of steel. The electric furnace may be therefore considered as being more economical than the ordinary air furnace, and would, barring some incidental losses not included in the calculation, be as regards economy of fuel nearly equal to the regenerative gas furnace. It has, however, the following advantages in its favour:—1st. That the degree of temperature attainable is theoretically unlimited. 2nd. That fusion is effected in a perfectly neutral atmosphere. 3rd. That the operation can be carried on in a laboratory without much preparation, and under the eye of the operator. 4th. That the limit of heat practically attainable with the use of ordinary refractory materials is very high, because the fusing material is at a higher temperature in the electric furnace than the crucible, whereas in ordinary fusion the temperature of the crucible exceeds that of the material fused within it. Without wishing to pretend that the electric furnace here represented is in a condition to supersede other furnaces for ordinary purposes, the advantages above indicated will make it a useful agent, I believe, for carrying on chemical reactions of various kinds at temperatures and under conditions which it has hitherto been impossible to secure.

(TO BE CONTINUED.)

4000. ELECTRO-MAGNETIC ENGINES, A. M. Clark.—Dated 18th November, 1879.—(A communication.) 6d. Engineer Feb 6 1880

This consists in an electro-magnetic motor of the use of one or more commutators upon a driving shaft or upon an independent shaft geared with said driving shaft, in combination with one or more driving wheels carrying each a series of electro-magnets.

COTTON BELTING.

A variety of materials have been tried to replace leather as a material for driving belts, but most of them are inferior in some respect, and cotton belts have not till quite recently been manufactured in such a manner as to justify their general adoption. Some of these have, however, lately been brought into the market, called Scandinavian belts, which appear to answer their purpose admirably well. They are simply a cotton fabric, which is lighter, more elastic, and more durable than leather, and, therefore, particularly adapted for high speeds. For most purposes, and especially for heavier belting of this kind, a coating of wood tar is found an advantage, while for small bands, such as are used for spinning machinery, the unprepared raw cotton belt is used. The cost of manufacture of these belts is very small as compared with leather, and by the peculiar method of weaving them, they do not fray out at the edge or break after being worn at the edge by running against a belt fork. The woven belts have, however, their disadvantages; they stretch and shrink more than leather belts; but once taken up sufficiently, they run more smoothly than leather, since they have but one joint and are perfectly uniform. When they get damp, they have the disadvantage of shrinking slightly. On their tensile strength Mr. Kirkaldy has made some experiments, and found that a cotton belt $3\frac{1}{2}$ in. wide broke under a load of 4187 lb., while a leather belt of good quality, 4 in. wide, was broken with 2100 lb. It is nevertheless advisable to use wider belts when replacing leather by cotton, since they are best used of ordinary thickness; this is, however, also in accordance with good practice in leather belting, thick belts having been found not to answer as well as thin wide belts, or at least requiring disproportionately large belt pulleys. In connexion with this subject, we may mention the American cotton belting, manufactured by Mr. M. Gandy, of Ansdell-street, Wapping, and which was largely employed at the Düsseldorf Exhibition, where it attracted considerable attention.

ELECTRICITY AS POWER.

BY FRANCIS P. UPTON, ESQ.

Science July 23 1881

In the early history of electrical science, many forms of engines were made, by which the power of electricity could be shown. Each was as wonderful as the other to the unthinking observer; for, without apparent combustion of fuel, work was done. We find, among the largest of these engines, one used in St. Petersburg, to drive a small boat, and one in this country to propel a train.

The United States Congress voted a sum of money to Prof. Page to carry on his experiments and he built a very efficient motor. After many experiments, though it was found that any amount of power could be obtained, yet the expense was so great as to make it of no practical value. In a small machine, the consumption of zinc might not be noticed, while in a large machine it would be found to burn exactly as the work was taken. Now that the doctrine of energy is clearly understood, the folly of the attempt can easily be seen. In a battery the fires are fed with an expensive metal. The energy developed by the zinc, thus used, was given to it artificially when it was reduced from the ore. In order to obtain a convenient fuel, both the coal and zinc ore must be mined, and the latter reduced, absorbing in the reduction a very small per cent. of the energy of the coal used in the process. Thus batteries for furnishing power consume a fuel at least fifty times more expensive than coal.

Besides the cost of fuel, the atmosphere, so to speak, in which the zinc burns, must be furnished to it artificially in the shape of acids or solutions. Though this has nothing to do with the theoretical cost, yet in practice, it is found to be the largest item of expense. It resembles furnishing a boiler with air made by a chemical process, so far as the economy of combustion is concerned. Yet the convenience and reliability of a battery to burn zinc has, where very small amounts of power are required, allowed of its use commercially, since steam is extremely difficult to manage in fractions of a horse power.

To-day the practice has been entirely reversed from what the first experimenters expected to realize. For electricity is now entirely made by means of steam engines to drive large motors. The last few years have brought the means of generating and using electrical currents to such a high state of perfection that power may be with economy transferred by them.

The loss in transferring is double; if a machine converts fifty per cent. of the power it receives from a staem engine, only fifty per cent. of that can be utilized, that is, twenty-five per cent of the original; thus wasting seventy-five parts out of each hundred of energy. A sixty per cent. machine can render effective thirty-six per cent.; an eighty per cent. machine can turn into useful work sixty-four per cent., and so on. This wasting of power in the transmission is more than counterbalanced in a great many cases by its delivery at the point where needed; for example, from a waterfall to a field for ploughing and threshing, as has been done in France; or from the shore to the water for the purpose of driving a torpedo boat, as has been done in this country.

Lately experiments have been made to show the application of electricity to railroads. Mr. Siemens, in Berlin, and Mr. Edison, at Menlo Park, are experimenting with electrical railroads. Mr. Edison uses the rails as conductors of electricity, the current going in one and returning in the other. The wheels are insulated, so that, by means of brushes on them, the electricity may be brought to the moter, which is on a carriage. The moter is simply one of Mr. Edison's generating machines, laid on its side, and connected by suitable mechanism to the axle of the driving wheels. On an experimental track of one-half mile length, a speed of twenty to thirty miles an hour has easily been reached, in spite of heavy grades and sharp curves.

For elevated and underground railroads, this method has many advantages; it does away with all the smoke and noise from the puffing of the locomotive, and substitutes for the many locomotives a few stationary engines scattered along the route. Mr. Edison feels very confident of success, since his troubles so far have all been in transferring the power from the armature to the driving wheels. He thinks that if the armature is only reliable, experiment will lead to proper mechanical devices for transferring the power from the quick-running armature to the slower driving wheels.

The road will be very useful in mountainous regions, since the engine is quite light and can be carried by trestle work and light earth work, over any country. The engine and boilers are not in this case put on wheels and required to push themselves over grades and around curves, but are placed in the valley below. Perhaps in many cases they may be done away with and water used to drive the generators.

For beach roads, in grand exhibitions, as feeders to main lines, and in many ways it is easy to see that use may be made of a properly constructed road. The gentle fluid, which has so quietly, for many years been the swift messenger of man, is now showing that it is also able to be a strong and lusty servant, and carry any load that it may be asked to take.

The Engineering & Mining Journal. Aug 27th 1881.

Transmission of Power by Electricity in Mining.—The first instance on record of the application of electricity for the transmission of power is reported from France. M. Mathet has submitted the details to the Société de l'Industrie Minérale. The St. Claude shaft at Blanzy was sunk to the depth of 500 meters (1040 feet), for the purpose of searching for a faulted portion of the coal seams, and a heading was run from it across the strata. When this heading had reached a length of 400 meters (1312 feet), the ventilation became so poor that the temperature at the face rose to 95° Fahr., and the miners could work only for a few hours. After some ineffectual attempts to improve the ventilation by simple means, it was decided to put in a fan 2·63 feet in diameter, and run it by power transmitted by electricity. An 8 to 10 horse-power portable engine was put up above ground, and with it a Gramme dynamo-electric machine was run at a speed of 1200 revolutions per minute. The electric current thus generated was conducted by a cable, consisting of seven 0·044-inch copper wires, to a second Gramme machine coupled directly with the fan, and placed in the heading near the shaft. Running at 700 to 800, it required $2\frac{1}{2}$ horse-power, the useful effect being at least 60 per cent. The temperature at the face was only lowered five degrees, but the men could work in 8-hour shifts. The return current was conducted from the underground machine by an iron wire cable. The cost of the whole plant is stated to have been only one third of what a machine for delivering compressed air to the heading would have required.

40

ELECTRO-TELEDYNAMICS.

BY PAGET HIGGS, LL.D., ASSOC. MEM. I.C.E.

Electrician Aug 7/1880

Teledynamics, or the science of transmission of power to a distance, has been confined in meaning to the conveyance of power by belting, or by ropes and pulleys. The transmissions of power by tubes of water, or of air, have neither, as far as I know, received specific titles. Whilst using the general term teledynamics in its commonly accepted and limited sense, I propose to name that correlative science in which electricity appears as the transmitting medium, as in the title of this paper; and, consistently, to term the science of hydraulic means of power-transmission, hydro-teledynamics; and that in which air is employed, pneum-teledynamics. These titles would convey the desired meanings, and prevent unnecessary repetition.

The employment of compressed air as a means of transmitting motive power has, in the last decade, received so great an advance as to become a chief tool in tunnel construction, and an important aid in mining and quarrying. The system, with its numerous defects, proves the want of power-transmission possessing greater facilities than the merely mechanical teledynamic method. Notwithstanding the loss of power through the heat manifested in the air during compression, to which must be added the loss by cold manifested during the expansion of the air, as well as the incidental losses due to effects of extraneous temperature, this system is being much extended in its application. The power transmitted by air is, to put it electrically, of low tension; the velocity of the current is affected in high degree by the walls of the pipe, and the engines, generative and motor, are bulky. For some of these reasons, the efficiency or the ratio of power received to that transmitted is low, rarely more than 30 per cent., and in practice averaging 25 per cent.

Hydraulic transmission has been limited in its application. Probably this has occurred from the great pressure in the pipes conveying the power, varying from 100 to 700lb. a square inch, from the difficulty of maintaining the pipes intact under this pressure, but chiefly from the slowness and indocile nature of the power received. For cranes and elevators hydraulic power has been and is transferred and accumulated with great economy; its generation at high tension is, however, expensive in first cost of plant.

To the third means of transmitting power by the intervention of electricity but desultory attention has been given, and very little is publicly known on the subject, whilst as a mechanical method both in adaptation and efficiency it can leave only small margin for complaint. It may, therefore, be not inadvisable to study more closely the advantages that electricity gives over water and air as transmission media.

In 1878 I presented to the Institution of Civil Engineers a paper, which was afterwards incorporated, with an account of other experiments, into book* form, descriptive of a series of measurements of power received and transmitted. I then showed that the efficiency of power received to that transmitted was one-half, provided regard was had to the maximum power obtainable from the second or receiving machine. This proviso, although stated, was given with insufficient definiteness, and the related ratios of efficiency were disregarded, making it appear as though 50 per cent. were the maximum relative efficiency. That this is not the case will presently be made clear.

In the system of transmission referred to similar dynamo-electric machines were employed, one being connected to a steam or water motor, from which power was initially derived to generate electricity in this the transmitting machine. The electricity so obtained was conducted by a cable of copper wire to a second or receiving machine, from which power was taken and observed on a dynamometer. This is the primitive arrangement for the machines in transmission by electricity, the electrical circuit comprising the exciting magnets and the revolving armature and the conducting wire in direct connection. Such an arrangement, although admitting of considerable facility for mathematical investigation is emphatically not the practically best, neither in the machines themselves, nor in their connection to the line-wire and related dimensions. The mathematical representation is, however, of the utmost simplicity under this system, and serves as a step in the study of complex and more efficient methods, such as the use of shunt magnet circuits on the Wheatstone principle, subjects of subsequent consideration.

It is now common knowledge that the revolving coils of the second machine generate a current, the electromotive force of which is of contrary sign to that of the current from the first machine. In this, the first machine represents a battery, the second a decomposing cell, and, for the electrical conditions of the circuit, we have, as current, the quotient of the difference of the electromotive forces by the sum of the resistances, or $\frac{E - e}{R + r + \rho}$, where E is the primary electromotive force, e the secondary, and R and r the resistances corresponding to the generators, ρ being that of the connecting wires. From Wheatstone's first elucidation of this formulated expression of polarisation phenomena to the present time innumerable investigators have considered the corresponding mechanical or heat values of the electrical conditions of any part of such circuit. It would remain only to see how these apply to the subject in hand; but that it is convenient to give one definite representation of such a deduction.

In an electric circuit comprised of the resistances R, R_1, R_2, &c., there may exist the electromotive forces $\pm E, \pm E_1, \pm E_2$, &c., and Q may be taken to represent the resultant current produced. The work of the electromotive forces will be represented by $\pm E\,Q$, $\pm E_1 Q$, $\pm E_2 Q$, &c., and the thermic value of the current passing in each of the resistances will be $Q^2 R$, $Q^2 R_1$, $Q^2 R_2$, &c. The sum of the terms of the latter series will be strictly equal to that of the former, although corresponding terms may differ greatly. To correspond with the earlier representation, three terms of the series may be taken to correspond to R, r, and ρ, and in the last portion of the circuit or in the conductor the electromotive force of the third term may be assumed to be nil. There then occurs the equation (substituting e for E_1)

$$Q\,E - Q\,e = Q^2(R + r + \rho),\ \text{or}$$
$$Q\,E = Q\,e + Q^2(R + r + \rho);$$

or, putting for $(E - e)$ the letter V and for $(R + r + \rho)$ the letter S,

$$Q\,E = \frac{V}{S}E + \frac{V}{S}e + \frac{V^2}{S} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1).$$

The first term is the total work of the source, the second the work of the motor, the third the thermic work lost in heating the wires. These expressions may be taken as in absolute units, and assigned their proper co-efficients for reduction to the ordinary units of work, tension, current, resistance, and heat.

If $e = 0$, the thermic or lost work is at a maximum; if $e = E$, the thermic work disappears. The variable value of e is a true representation of the state of the second machine or the motor which is at rest when $e = 0$. Between these two limits there is an algebraic maximum, when $e = \frac{E}{2}$, and when there is an equal distribution between thermic work and the motor's work. As the variable e exceeds $\frac{E}{2}$, the motor's work diminishes in absolute value, but increases in value relatively to the work expended, to the limit $e = E$. This absolute value of work reclaimed is obviously determined, in relation to the work expended, by the ratio $\frac{e}{E}$, and its relation to its maximum is $= 4\frac{e}{E}\left(1 - \frac{e}{E}\right)$.

Thus, if the electromotive force of the generator be a fixed quantity, the relative efficiency cannot be increased beyond ½ without diminishing the absolute value of the work reclaimed; for any fixed relative efficiency the work reclaimed can be increased to any given value, provided the generator's electromotive force can also be increased, as when absorbing a fixed mechanical power. Only under this condition can the work reclaimed, at the theoretical limit, equal the work expended.

These two cases, apparently incompatible, are not really so, and the inconsistency disappears on a close study of the question, which is not generally well understood. Its solution, as here given, unerringly points out to the constructor the principle to be followed in building machines for the transmission of power.

41

ELECTRICITY AS A MOTIVE POWER.

Telegraphic June 15 1880

The following letter, concerning certain experiments on the application of electricity as a motive power, appeared in a late number of the *Times*:—

"About this time last year I sent you a short account of some experiments by Mr. C. Felix, of Sermaize (Marne). This gentleman has continued his experiments, and at the Regional Agricultural Show now being held in this town, his apparatus has been shown at work. It consists of the ordinary 'Gramme' machine, worked by a semi-portable engine, furnished by Boulet and Co., Faubourg Poissonnière, Paris. Two coils of wire convey the power to a smaller Gramme fixed on a framework of wood, movable on four wheels. This acts as an intermediate motion, and has two broad-face pulleys, one on each side, 20-inch and 14-inch diameter; these run at a speed, if required, of 800 a minute, the latter driving a 6 horse-power thrashing machine at a considerable distance from the main power. The 20-inch pulley might be used for driving any other machine if required.

"The ploughing apparatus, which is at work at the same time, in the field adjoining, consists of a similar Gramme machine, fixed in a very solid framework of wrought iron, about 6ft. long by 5ft. wide, standing on wheels, 3ft. 6in. diameter, in front, and 4ft. 6in. behind. Shafts and a locking gear are also attached. There are two of these at work for ploughing, as in Fowler's double tackle.

"The Gramme has two pulleys, as I before stated, one on each side. These, by friction rollers, work the drum of the ploughing tackle, round which the steel wire rope is coiled, the drum being in the centre of the carriage, the wire escaping from the lower part near the ground, and guided in its course by two flat rollers.

"The plough is one of Howard's double-furrow, supplied by Mr. Pilter, Paris, and fitted for the purpose.

"The power is conveyed in an instant from the main power in the showyard by a coil of wire on wooden reels, long enough to reach several fields off.

"The plough worked clean and regularly about seven or eight inches deep. The ground was very hard and uneven, as this part of France is suffering very much from want of rain. One man is required to each machine, and one man to the plough, three in all. The ploughing was not very straight, for, as the people crowded about the plough and on the ropes, the driver could not see where he was going. Directly the plough reached the end of its course, it was lowered and returned, the machine being thrown out of gear and reversed with the greatest ease.

"The machines are also advanced or retired without the least difficulty. When this is done, the friction rollers are detached, and the power conveyed to a chain and notched wheel, which move the machine rapidly forward as the ploughing work progresses.

"The manager, Mr. Ducret, states it would be just as easy to work a three or four furrow plough as this double, but the holdings being small in this country it is not necessary.

"Mr. Felix, who is here superintending his invention, has a large sugar factory at Sermaize, and there may be seen his various machines worked by electricity, as we indeed see in this showyard.

"The officials connected with the show and many others were present, and the greatest interest was manifested in the trials. Electricity as a motive power is only in its infancy, but who can help feeling sanguine as to its future?

"J. S. Cockshdge, of Stowmarket.

"Bar-le-Duc, France, May 32."

New Instances of Magnetic Attraction.—By M. Ader, in *Comptes Rendus*, 1880, p. 864. When making his researches on magnetic quality of wood, paper, and other light bodies, the author made pith balls 5 mm. in diameter, and found that the permanent magnet of Jamin (which supports 100 kilos.), with two small armatures, having a space between of 2 mm., attracted the suspended pith from a distance of 3 or 4 mm. And when once the ball had adhered to it, only rough shaking of the magnet was sufficient to release the ball from its position. The magnet alone sufficed to attract the pith, but in all experiments attraction was much stronger when to the poles of the magnet were added the said soft iron armatures, in close proximity to one another.

ELECTRICAL HEAT AND POWER.

34 Sc. Am. Suppl. Aug 14 1880

There seems to be little or no doubt that the time is not far distant when we shall be enabled to utilize the mysterious forces of electricity for heat as well as for light, and for mechanical propulsion as well as for metallic deposition. It is not possible to foretell the exact period when these things will be accounted among the accomplished facts, but it appears to be likely that the time is not far distant. The more we learn of electricity, the more its capabilities increase, and we no sooner make it our servant in one capacity than we are led to speculate upon its possible utility in others. A lecture delivered the other evening by Dr. C. W. Siemens is replete with facts and suggestions of this nature. Dr. Siemens, in the first place, has tested the electric arc as a means of fusing metals with the most complete success. He has melted one gramme of steel in this way with units of electric power amounting to within a fraction of the heat energy residing within a gramme of ordinary coal; that is to say, by means of a dynamo-electric machine, worked by a steam engine, one pound of coal is rendered capable of melting one pound of mild steel. At Sheffield, in the ordinary air furnace, three tons of best Durham coke are consumed in melting one ton of mild steel in crucibles. Further than this, the fusion by electricity attains heat which is practically unlimited; is effected in a perfectly neutral atmosphere; can be readily conducted; the fusing materials within, and of a higher temperature than the crucible—contrary to the results of ordinary fusion. Dr. Siemens has also ascertained that the electric light has the effect of causing plants, vegetables, etc., to grow to a finer development than sunlight, and, he is so convinced on this head that he is specially applying the light at his country residence. With respect to the application of the dynamo electric current to mechanical propulsion, Dr. Siemens quotes the example of a narrow-gauge railway, laid down in a circle nine hundred yards in circumference, at Berlin, by his brother, Dr. Werner Siemens. Upon this railway a train of three or four carriages has been run by means of a dynamo-electric machine so fixed as to give the necessary motion. The two rails being placed on wooden sleepers were sufficiently insulated to serve for electric conductors, the driving axle being also insulated, so that a current passing through one rail could pass into the driving wheel, thence through the second rail to the station, where both rails were connected with another dynamo-electric machine which was driven by an engine. This little railway worked most successfully, the trains running from fifteen to twenty miles an hour. Its operations have suggested a similar line on a larger scale within the city of Berlin, and Dr. Siemens thinks we shall shortly have electric tramways on roads, as well as in connection with mines. In adits or tunnels the entire freedom from smoke of the electro-motor would be greatly in its favor—in no case more so than on the underground sections of the London railways. So forcibly does this advantage appear that Dr. Siemens states the administration of the St. Gothard tunnel seriously contemplate the use of electricity for running trains through that gigantic undertaking. Should this really be done a great step forward would be made, and we should be so much the nearer the realization of that long-foretold era when all the principal operations of mechanics will be performed by electricity.—*Ironmonger.*

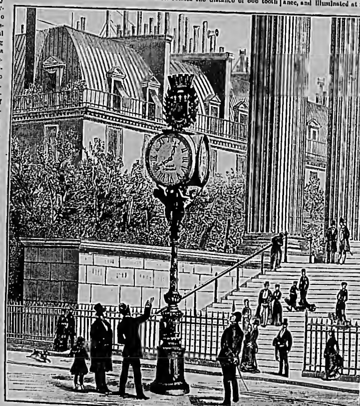
Pneumatic Clocks.

The accompanying illustration gives a representation of a street clock operated on the pneumatic principle, a convenient system which has been largely adopted in Paris and other cities of continental Europe. Compressed air in this plan is made use of to operate all the clocks of a city or district simultaneously, precisely as electricity is similarly employed. The parts of the pneumatic clock system are, the central clock, the receiving clocks, and the tubes and intermediate mechanism for conveying compressed air to the receiving clocks. At the central station a reservoir of compressed air is provided, containing about 25 cubic feet at about five atmospheres pressure. From this reservoir the compressed air is conducted to a second reservoir, in which its pressure is regulated at seven-tenths ($^7/_{10}$) of an atmosphere. Every minute the distributing reservoir is placed in communication with the distributing tubes by the action of the mechanism of the central or distributing clock. The central station is provided with several of these clocks, so that if one should become disordered another can be set in operation within a few seconds. A distributing tube connects with the several mains which convey the compressed air into the various districts where pneumatic clocks are provided. The mains are of wrought iron, $1^1/_{16}$ inches in diameter, and are connected with lead tubes three-5ths of an inch in diameter, for conveying the air into the houses where necessary. With a pressure of seven-10ths of an atmosphere, it is found that any required number of clocks can be operated at a distance of from one to two miles from the central station.

The action of the receiving clocks is about as follows: A small bellows, resembling that used in pneumatic call-bells, is in communication with the tubes conducting the compressed air from the central office. Every minute the pressure of the air raises the bellows, and a rod attached to the upper bellows-head actuates a lever which engages with a wheel provided with 60 teeth, which is rigidly secured to the minute-hand arbor. The wheel rotates the distance of one tooth every minute, and a weighted pawl on the other side of the dial checks this movement. The hour-hand is rotated by means of the usual dial wheels. By means of a second bellows the clock may be arranged to strike. The ordinary spring and weight clocks can be easily transformed into pneumatic receiving clocks.

The mechanism of the receiving clock is alike in all cases, and is entirely independent of the size of the dial or the location of the clock. It is asserted that many of the principal hotels, railway depots, public buildings, courts and the like in Paris, are provided with clocks operated on the principle above described. One of the most useful applications of the system is that shown in connection with a street clock. A number of these pillar clocks, of very ornamental appearance, and illuminated at night, are said to have been erected in that city.



PNEUMATIC CLOCK IN PARIS.

We are informed that it is the intention of a company that has lately been organised, to introduce pneumatic clocks into American cities.

ELECTRO-MOTORS.

7

THEIR POWER AND RETURN.

J. Hospitalier.

The transmission of force from a distance, electric ploughing, the electric railroad, etc., have made electric motors and the conditions of maximum work and maximum return, quite the order of the day. In a previous article on the available force in batteries, we have determined, for the most usual forms, the quantity of energy that could be furnished by a certain number of elements in an external circuit of proper resistance, supposing no polarization and without variation of the internal resistance.

Is this maximum of available work entirely convertible into effective work? It is not, and we will show how this maximum should be reduced when a given electric energy is to be transformed into mechanical force.

Let us suppose, for instance, in numbers, which always strike the attention more than formulas, that we have a source of electricity of 100 volts, with an internal resistance of 1 ohm. It would be easy to realize the conditions by employing an electro-dynamic machine, separately excited, or 100 very large Bunsen cups, arranged for tension in 2 parallel series of 50 each. Putting into the circuit an external resistance equal to the internal, and supposing no polarization to exist and no change in the internal resistance, we obtain as elements for the electric circulation:

E.—Electro motive force	=	100 volts.
r.—Internal resistance	=	1 ohm.
R.—Exterior resistance	=	1 ohm.
$(r+R)$—Total resistance	=	2 ohms.

$$Q.\text{—Quantity } \frac{E}{r+R} = \frac{100}{1+1} = 50 \text{ webers.}$$

In these conditions we know that we have in the external circuit the maximum of available work, as deduced from the formula of Joule:

$$W = 10\, Q^2R \text{ meg-ergs} \qquad (a)$$

$$\text{or } W = \frac{Q^2R}{9.81} \text{ kilogram-meters} \qquad (b)$$

In the case before us we have:

$$W = 10 \times 50^2 \times 1 = 25{,}000 \text{ meg-ergs} \quad (1)$$

What can we do with this available electric work? If we make it traverse an inert wire it will heat it. All the electric energy will be transformed into heat, and in this wire will be developed a certain number of calorics C, per second:

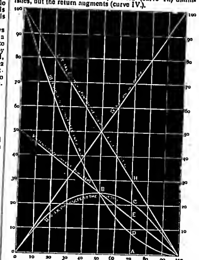
$$C = \frac{Q^2R}{9.81} \times \frac{1}{A}. \qquad (c)$$

A being the mechanical equivalent of heat 424.

Let us substitute for the inert resistance of a wire, an electro-motor of equal resistance with the wire, say 1 ohm in this particular case. Let us suppose this motor to be one of Gramme's magneto-electric machines, and that the resistance of the armature is equal to 1 ohm. If we put a break on the armature to prevent it turning under the influence of the passing current, we will not have any of the original conditions changed; the wire of the armature will be heated by the current, and a number of calorics C will be produced equal to that developed in the wire. Now let us make the armature turn under the action of the electric current. The rotary motion of this armature will develop a certain electro-motive force E', inverse to that emanating from the source of electricity E, varying with the speed of the motor. It results in a diminution of the current, and can be expressed at each instant by the formula:

$$Q^1 = \frac{E - E'}{r + R}. \quad (d)$$

Hence the rotation of the motor diminishes the intensity of the current (and consequently the work of the motor) if a machine is employed as a source of electricity, or the consumption of zinc, if you employ a battery. The diagram shows how the different elements vary when the speed of the motor varies from zero (where the work developed is null) to a velocity such that the opposing electro-motive force E, which it develops, becomes equal to the electro-motive force of the source. It is seen that the energy expended by the source of electricity diminishes from the time the motor begins to turn (curve I.); similarly, the intensity of the current (curve V.) diminishes to zero when E and E' become equal. Curve II. represents the work developed by the motor at different speeds. Let us suppose these speeds are proportional to the electro-motive forces—a hypothesis easily verified in a well constructed magneto-electric machine—then we see, by the diagram, an augmentation of the work produced, up to a point where the speed of the motor becomes 50. At this moment the work done is at a maximum, and represents but 50 per cent. of the work expended by the source of electricity. The energy converted into work (curve III.) is equal to what is unconverted (curve II.). If the speed augments beyond this point the work produced (curve II.) diminishes, but the return augments (curve IV.).



The work produced and the return are hence perfectly distinct things which are too often confounded. There is no impossibility in making the motor return 80 per cent. of the work expended by the source of electricity, on condition you do not make this source produce all the work which it can furnish. When, at the limit, the work produced becomes null, the return becomes equal to 1. The same conclusion is arrived at on comparing curves I. and II. It is thus seen that energy not converted into work, diminishes more rapidly than the total energy expended by the source of electricity. When the motor is at rest, the work is zero, all energy being transformed into heat. When $E' = \frac{E}{2}$, the diagram shows that the work is equal to the loss; curves II. and III. cut each other at B and the return is 50 per cent. Several consequences result from this. If you wish to obtain the *greatest* results from any given source of electricity, the electro-motor, turning at normal speed, must be so arranged as to develop a counter electro-motive force equal to the half of the original source. If the *best* results are wanted greater speed is required, by which a return in work is gained with a corresponding loss in the quantity of work produced.

Curves III. and IV. show why an electro-motor heats more when stopped than when turning at a certain speed; the intensity of the current is greater in the first case than

49

VELOCITY OF ELECTRICITY.

ELECTRICIAN, AUGUST 21, 1880.

A correspondent, dating his letter from Marseilles, writes to request "a lucid answer with reference to the ratio between the speed of electricity and that of light." As it is probable that a statement in "Answers to Correspondents" to the effect that no such ratio exists, or, at least, that it is impossible to determine it, might be considered insufficiently lucid, we purpose devoting a little space under this heading to the explanation of the fact as here stated. Many young electricians, besides our correspondent, appear to be under the impression that electricity travels with an assignable and constant velocity, such as that of 288,000 miles per second, which was the speed observed by Professor Wheatstone in his celebrated experiments at King's College, from which, unfortunately, some very erroneous conclusions were deduced; and it cannot be too widely made known that, as Mr. Fleeming Jenkin observes, "the same quantity of electricity may, under different circumstances, be made to traverse the same distance with almost infinitely differently velocities," and that, in fact, there is no velocity proper or peculiar to electricity. And in these days it should be understood, also, that the results obtained in Wheatstone's experiments were not "conclusively in favour of the double fluid hypothesis as to the nature of electricity," and that they are equally compatible with the single fluid, or, indeed, with any other hypothesis that has yet been advanced in this relation.

The destinction to be made between the *velocity of electricity* and the *velocity with which a given quantity of electricity can be transmitted* requires, in the first place, to be insisted upon in order to arrive at a logical conception of the real questions involved. Now, it may at once be stated that what is meant by the term "velocity of electricity" has never yet been defined, and that the velocity with which a given quantity of electricity can be transmitted varies "directly as the inductive resistance and inversely as the conductive resistance of the circuit through which the transmission takes place."* Thus, taking, as is usual, inductive capacity (F) in farads, instead of its reciprocal "inductive resistance," the *time* (t) in which a condenser, when circuited, will lose any given fraction of its charge is

$$t = R \cdot F \cdot k \text{ seconds};$$

R being here the resistance in ohms,† and k a constant which depends only upon the ratio between the final and initial charges. Quoting from the same authority: "if this ratio equal ·367, k is unity, and, if it equal ½, k is ·693." Therefore any condenser will lose 693 thousandths of its charge in R F seconds, and any condenser will fall to half charge in R·F × ·693 seconds. And although an experiment with an ordinary condenser represents a simplified case, whereas an experiment with an elongated condenser such as a submarine cable presents conditions of greater complexity, it is to be observed that all cases of electrical transmission necessarily involve a conductor or electrical resistance and inductive capacity or a condenser. Since velocity is measured by the length of the conductor divided by the time, it will be seen that data may be obtained for calculating the speed at which a given quantity of electricity may be transmitted under any given conditions. And if we adopt the convenient plan of measuring velocity by the product of the length of wire (L) in knots into the number of elementary signals that can be transmitted per second, the "given quantity of electricity" being here that which will produce a signal on the instrument employed, then, according to the data given by Messrs. Clark and Sabine,‡ the velocity of transmission, with the mirror instrument, would be

$$V = \frac{433 \times L}{RF};$$

the product RF being, as before, either ohms into farads or megohms into microfarads.

Prior to the year 18[?]4, it was held that the "velocity of electricity" was so great as not, under any circumstances, to be measurable. And the first result of Wheatstone's experiments was to show that the duration of the discharge from a Leyden jar, when the latter was "short-circuited," was not so much as the millionth part of a second. In these experiments the image of an electric spark was received upon a mirror in rapid rotation; one spark passing at each rotation, when the mirror was in a position to render it conveniently visible. With a high velocity, the image of a spark having any measurable duration would appear elongated; the length becoming greater as the velocity was increased. Now, with the short-circuited jar no elongation in the image of the spark could be perceived; but when the jar was discharged through a copper wire half a mile in length the elongation became very appreciable. This result was sufficient to show that the propagation of electricity is not instantaneous: other arrangements, referred to as follows in Noad's "Student's Text Book of Electricity," had to be made in order to determine the velocity of transmission. "A jar was discharged through a copper wire half a mile in length, interrupted both in the middle and at the two extremities so as to give three distinct sparks. The deviation of half a degree between the two extreme sparks would indicate a velocity of 576,000 miles in a second. This estimated velocity is on the supposition that the electricity passes from one end of the wire to the other; if, however, according to the *two-fluid* theory, the two electricities travel simultaneously from the two ends of the wire, the two external sparks will keep their relative positions; the middle one alone being deflected, and the velocity measured will be only one-half that in the former case, viz: 288,000 miles in a second. The following were the results actually obtained:—In all cases when the velocity of the mirror exceeded a certain limit the three sparks were elongated into three parallel lines, and the lengths became greater as the velocity of the mirror was increased. The greatest elongation observed was about 24°, indicating a duration of about the 21,000th part of a second.

ENGINEERING.

54

GAS ENGINES.

TO THE EDITOR OF ENGINEERING.

SIR,—As an old subscriber to your paper, will you kindly allow me a few lines in answer to Mr. Linton's paper on the gas engine, which appeared in your paper of July 30th, and which will bear out very fully some of Mr. Linton's remarks.

I put down an 8 horse power Otto engine for a client in February, 1878, since which time it has run constantly with the exception of holidays. During that time the only repairs done or necessary to the engine have been having slides refaced twice, this costing with railway carriage from Manchester 23s. each, in all 46s. The engine is run sometimes at full power, sometimes at less, and I have found it admirably adapted for a variable load. The engine under various conditions runs steadily at 160 per minute. The average attendance I have found to be one-quarter of an hour per day, and with the system of lubrication employed no further attendance is necessary.

Having very clean gas in this town, I have not once required to remove the piston, and the slides only require to be cleaned once every month.

Regarding water supply—I have found it best to keep a little running into cistern all the day. I have found the engine requires 17 cubic feet of gas per horse power per hour, and from my experience think the depreciation allowed by Mr. Linton too high.

Mr. Linton will find that the oscillation he mentions can be overcome by putting in another gas bag between the meter and the engine, two bags I have found placed somewhat apart being better than one large one. When the pressure is increased, as during the night, this pulsation does not occur. The side light should also be taken from a separate pipe; if this is not possible, it should be taken at some distance from main connexion, as it is highly necessary that the side light should burn steadily.

I have since 1878 fitted up a number of these engines in the district, and since gas managers have overcome the prejudice against their use, get all encouragement from them.

In this letter I have not gone into figures, as your readers can judge as to relative value of steam and gas engines from Mr. Linton's paper, the allowance he has made for gas engine being in my opinion too high.

I shall be glad to give any of your numerous readers any other details they may wish, and remain

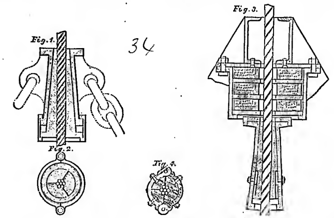
Yours faithfully,
JOHN W. LOGAN.

Berwick-on-Tweed, August 9, 1880.

49

WIRE ROPE CONNECTIONS.

THE connections commonly in use for securing wire rope to hoist cages consist in either bending the end of the rope into a loop, putting an iron ring into it, and lashing or clamping the end against the side of the rope, or the end of the rope passes through a conical sleeve, and a tapered wedge is then driven in between the wires of the rope, forcing the latter against the sides of the sleeve, and thus firmly uniting the two, or the wires in the end of the rope are turned back, the rope being passed through a conical sleeve, and the space run in with lead. All these methods are applicable where the end of a rope is to be fastened to a cage; but in all cases this end is destroyed, and the two cannot be separated—for repairs, for instance—without renewing the mode of connection after the previous end has been cut off. In cases where, as it is at present not uncommonly the case, a continuous rope is used partly for the purpose of balancing the weight of the rope, partly for working with the same rope from different stages, the modes of connection above referred to are not suitable, and some other means of making the connection have to be employed. The principal conditions which a coupling for this purpose has to fulfill are: first, to form a safe and firm connection, and, secondly, one which in no way injures the wire rope, since an injured place in the middle of a rope cannot well be repaired. It is, moreover, desirable that this coupling should be capable of being easily and rapidly put into or out of operation. A coupling which fulfills these requirements, and has for some time been in practical use in Rhenish Prussia, is shown by its inventor, Mr. F. Baumann, at the Dusseldorf Exhibition, and we understand that it is already applied to a considerable extent in the Rhenish and Westphalian mining districts.



BAUMANN'S WIRE ROPE CONNECTION FOR MINING CAGES.

This coupling is shown in its simplest form in Figs. 1 and 2, from which it will be seen that it consists of an outer conical casing fixed to the cross bar of the cage. Through this casing the rope passes, it being held in position by three or more conical pieces exactly fitting the casing externally, and the windings of the rope internally. The weight of the cage will naturally exert a pressure on the rope which increases with the load. These fitting pieces are cast in white metal or brass round the rope, and the coupling has stood some of the severest tests; having been tried in one case with a in. rope, consisting of thirty wires, 0·1 in. in diameter, well greased, and the cage loaded till the rope broke about 10 ft. above the coupling under a load of 7½ tons; the place where the coupling had gripped the rope could not, after the oil had been wiped off, be found, showing that the rope does not in any way suffer, and that no slip had taken place.

A hinged ring connecting the fitting pieces with the casing prevents the coupling from disengaging when the cage sets off at the bottom. An arrangement of this construction has been in use at the Friedrichsthal mines for over a year, and has been weekly shunted about several times, but has up to the present given every satisfaction.

To entirely avoid the necessity of care in adjusting this coupling, which is indispensable in the arrangement above described, and to obtain a still more rapid disconnection, Mr. Baumann has designed the arrangement shown in Figs. 3 and 4. The packing pieces here consist of four pieces with dovetailed slots, into which fit the heads of four bolts. The casing outside is made in two pieces hinged together, and this cannot be closed over the rope until the "lay" of the rope thoroughly fits into the grooves. An india-rubber buffer is added to avoid the sudden shock on the rope. In steel ropes, suitably arranged to carry an electric cable inside, communication can easily be established between the cage and the engine room. This system certainly possesses great advantages where a continuous rope is used, but even for a single rope, where disconnecting is occasionally necessary, it is a very handy arrangement.—*Engineering.*

Motive Powers of the Future.

Builder Sept 1880

A suggestive paper was recently read before the Liverpool Engineering Society on the "Utilization of the Tides," by Mr. Oates, of Bradford. He was of opinion that although the coal supply of England would last for a long time to come, yet that ultimately the power of the tides would outrival all other sources of mechanical power. After pointing out that the ways of utilising the tides were innumerable, and describing the construction of the tidal dam with suitable converters of the power, such as turbines in openings of the dam, working air-compressing or magneto-electric machines, he stated that the necessity for large conservators for storing the power between the tides would be the greatest difficulty in utilising their power. A description of how this could be done, and the power rendered constant, was given. The means of conveying the power to a distance was then considered, air and water pressure and electricity being suggested. With regard to the latter, Mr. Oates believed that the "age of steam" had reached its zenith, and that the "age of electricity" had dawned; but should there be difficulty in conveying the power to a distance, he suggested that manufactories might be built adjacent to suitable tidal sites.

34

Electricity from River Currents.

An inventor of this city proposes to utilize the swift current of rivers by systems of anchored floats carrying current wheels connected with electro-dynamo-machines. The electricity thus generated might be conveyed to factories on the shores and set to work by means of electro-motors: or it might be used for lighting towns, or even for running trains on railways.

34

WIRE ROPE TRANSMISSION.—Among the recent improvements in the way of transmitting power for long distances, is the substitution of belts by endless wire ropes running at a high speed. Just where the belt becomes too long for economy there the rope steps in. In place of a flat-faced pulley a narrow sheave, with a deep, flaring groove, is used, the groove being filled out, or lined rather with leather, oakum, India rubber, or some other soft substance, to save the rope. The essential points are a large sheave, running at a considerable velocity, and a light rope. When the distance exceeds 400 ft., a double-grooved wheel is used, and a second endless rope transmits the power 400 ft. further, and so on. The loss by friction is said to be only 8% per mile. If it is required to transmit 300 horse power by means of a wire rope, the size of rope required will be one inch in diameter, running 4,020 ft. per minute over a wheel 14½ ft. in diameter, making 108 revolutions per minute. One is thus enabled, at a small expense, to transmit power in any direction.

Mr. BISSINGER, M.E., of Carlsruhe, gives the following results as obtained in his examinations of the several motors in regard to their relative cost per horse-power for each hour. It will be observed that the examination pertained principally to small motors. The relative cost per effective horse-power per hour is as follows:—100 h.-p. steam engine, 7·6; 2 h.-p. steam engine, 44·3; 2 h.-p. Lemann's caloric engine, 26·5; 2 h.-p. Hock's motor, 40·0; 2 h.-p. Otto gas engine, 26·4; 2

THE FUTURE OF AMERICAN COTTON MANUFACTURE.—THE POSSIBILITIES OF SOUTHERN WATER POWER, &c.

34

Scientific American Nov 27 1880

IN a communication from Atlanta, Ga., dated October 31, Mr. Henry N. Meigs writes as follows in the New York *Herald:*

There are now some 10,000,000 cotton spindles operated in the Union. In the year 1900, only nineteen years away, there will be 20,000,000 needed, because the increase of population and of exportation of American goods will demand them. The population, as ascertained by the recent census, is, in round numbers, 50,000,000. In 1870 it was 38,000,000—an increase of thirty-one and a half per cent. in ten years. The same rate of increase for the next two decades will make it 91,000,000. To sustain this estimate let me suggest that from 1790 to 1820 and for each succeeding period of thirty years the "Compendium United States Census" shows an average increase of over one hundred and forty per cent. This ratio applied to the 38,000,000 of 1870 gives us over 90,000,000 in 1900—thirty years later. So it appears that twenty years hence we may expect a population nearly double that of the present year as just ascertained. If this estimate of population fails the increased tendency of the people toward manufactures will compensate for the smaller number of the population. Will not two pounds of cotton goods be required from United States mills in 1900 for one pound now produced? If this is correct 20,000,000 of spindles will be required.

During the interval of nineteen years most of the spindles now in use will be worn out or otherwise destroyed. Let us say that 5,000,000 must be replaced and 10,000,000 more must be supplied—in all 15,000,000, with all their preparatory and following machinery—before the end of this century. Is this extravagant? I think not. One-half of the 7,000,000 at work in 1870 were operated by steam, the other half by water power. The *Financial Chronicle* reports the home consumption last year at 1,800,000 bales, averaging 481 pounds each. This is equivalent to over 865,000,000 pounds. If the ratio of 1870 has been maintained some 430,000,000 pounds have been manufactured by steam in 1870 and 1880. Is this economical? It pays, certainly; but does it pay as well as with water power? The requisite power for 1,000 spindles, with looms, has been variously estimated at fifteen to twenty-five horse power. As all speeds have been accelerated since the introduction of the American ring spindle, let us take (in medio) the ratio of twenty horse power. For 20,000,000 of spindles, with looms, this ratio demands 400,000 horse power.

The Utilizing of the Tides.

A Philadelphia engineer has invented, it is claimed, a machine by which the power of the tides can be utilized. Numerous plans have been proposed for the accomplishment of this most desirable end, but only under exceptional conditions have they been practical or economical. If the new device can harness the tide in any fair channel, so as to convert any considerable portion of the vast power into working force, the inventor will rank among the great benefactors of humanity. Emerson says somewhere: Hitch your wagon to a star. A device for utilizing mechanically the free tides, as they sweep along our shores, would come next to that, since it would enable us, through converters and carriers of electricity, to hitch our wagons to the sun and moon.

AN ENORMOUS RUBBER BELT.

The contract for supplying the rubber belting to be used by the largest elevator in the world, now being erected near Baltimore, has been awarded to the Gutta Percha and Rubber Manufacturing Company, New York. The elevator will require one hundred belts. The main driving belt will be five feet wide, eight plies in thickness, about two hundred and twelve feet long, and will weigh over one and a half tons. This is by many hundred pounds the heaviest rubber belt ever made.

TRANSMISSION OF HEAT AND POWER.

TO THE EDITOR OF ENGINEERING.

SIR,—I have thought it would be of interest to give you some particulars of experiments which have been carried out in the United States relative to the transmission of heat and power to a distance from the generator. I have searched amongst my papers for the experiments of the late Mr. Max Hjortsberg in vain, so that unfortunately I can only offer you at present a very brief description of what has been done, and which from an engineering point of view will be, I fear, very incomplete.

There are two systems which are receiving attention in the States, both of them being intended to be used for the supply of heat and small power to the inhabitants of cities, viz., steam and highly heated water.

Mr. Holly, the inventor of the high-pressure pumping system, was the first to experiment on a large scale as to the ability of carrying steam for considerable distances. About three years ago he put down a line of pipes in his native town of Lockport, New York, with comparative success. He has in several places put down plant for the same purpose, but the most successful one has been at Hartford, Connecticut, as I mentioned in my former letter. There Mr. Bardett Loomis, aided by his friends, determined to put down a plant differing from Holly's practice in several material points, and experience has shown that his judgment was correct. He carried steam through about a mile and a half of pipes, ranging from 6 in. to 2½ in. in diameter, under a boiler pressure of 70 lb., and he informs me that at the farther end of the plant, the pressure is reduced only 2 lb., but unfortunately he does not give how much steam passed through the pipes at that point, so that this figure cannot be utilised for determining the loss in carrying the steam so great a distance. The covering he uses for the pipes is most effective, consisting of logs, bored and turned so as to allow of a 2 in. air space between the pipe and the log. These logs are creosoted and driven one within the other tightly, so as to prevent any circulation of air. At intervals of 100 ft. expansion joints are provided, which are placed inside cast-iron manholes, also kept air-tight, the logs being driven into holes formed in the sides. The forms of the expansion joints, reducing valves, and traps are all novel, but I will not inflict a description of them upon you here. By this plan all the water of condensation is returned to the boilers by means of a pipe laid alongside the steam pipes, and covered in a similar manner, and into which the water of condensation from the various buildings is trapped. This gives the material saving not only of about 150 deg. of heat, but also of the water, which latter, in towns where it has to be purchased from water companies effects a considerable economy. He informs me that wherever his pipes are laid the inhabitants nearly all decide to take the heat supplied in preference to continuing their old systems of heating by hot air derived from cast-iron stoves, or by the old method of stoves and open fires. He farther tells me that although only started last October, he is now heating over 6,000,000 cubic feet of room space, and driving about 150 horse power nominal in the shape of small engines where the cost of putting down boilers, together with the extra risk for insurance would prevent them from being used. There is very little doubt that before many years are passed every city of any size in the United States where it is cold enough to require heat in the winter will have some general system of heating.

The hot-water system spoken of has been claimed by the inventor, Mr. W. E. Prall, of New York, to be a superior means of doing what has hitherto been done by steam. He contends that water is a better medium for the storage and conveyance of heat than steam, and he claims as superior features the facts that pumps can be used to circulate the water at seasons of the year when very little heat is being taken from the mains, but that little requiring to be of a sufficient temperature for cooking, &c.

His plan is to heat water to a temperature of about 400 deg., and allow it to circulate through pipes which have communication with a circulating pump. He also provides a return pipe for the water of condensation. Mr. Max Hjortsberg after carrying out the series of experiments mentioned, came to the conclusion that in his opinion Prall's system was vastly superior for its intended purpose than any steam system. He laid down about a mile of piping conveying the water to buildings, where, after reducing the pressure, he used the steam generated for running the engine of a factory and the unconverted water for heating the rooms, stating to me that the loss at the end of the pipe furthest away from the generator was surprisingly small.

Mr. Prall is about to lay a plant in New York City, and I await the results with very considerable interest, and shall be happy from time to time, as they proceed with the work, to give you information respecting it. The question of measuring or metering the amount of heat and power supplied to customers is one still unsettled. Mr. Holly designed a steam meter, which consisted of some clockwork actuating a small screw shaft, the speed of this shaft being controlled by a link worked from a diaphragm which rose or fell with the pressure of the steam in the pipes giving a greater or lesser throw to a pawl working in a ratchet. This, however, could not have been successful from the fact that he did not charge by its reading, and has in most cases thrown them out. Mr. Prall claims that by means of a specially made water meter he can register the amount of water that is conveyed into a building before it passes the reducing valve, and by this means can measure accurately enough for charging.

The advantages of using these systems are numerous. The heat supplied for warming buildings is much healthier than that produced by ordinary means. The dirt and dust consequent on using open grates and stoves is avoided. The risk of fire is greatly reduced, and the cost of heating a given amount of space is very much smaller when supplied wholesale. For running small powers, especially in a country where gas is charged at exorbitant rates, it is invaluable, and these facts being appreciated by the people, there is generally very little difficulty found in obtaining custom.

Trusting that these few facts, which want of time prevents my putting in a more interesting shape, will be of some interest,

I remain, Sir, yours obediently,
HARRY OLRICK.

TRANSMISSION OF ELECTRICAL FORCE.

IT is claimed that by a new device mechanical energy can be transmitted from one distant point to another by means of electrical conductors, so that a descending stream anywhere can be utilized as a source of mechanical power in towns and cities ten or fifty miles distant. This invention is claimed by an Englishman, Dr. Hincks, now in this country, who has constructed the apparatus, and has formed in New York a company with a large capital, to put it in practical operation. The construction of small motors propelled by electricity has been accomplished for many years; ever since, in fact, the discovery of the electro-magnet and methods of changing polarity by automatic devices. The new motor claims to be very much more than a plaything; a power, in fact, which is capable of propelling heavy machinery and doing the work of steam in all its varied applications. We were promised last winter a private *séance* in this city with this new wonder, but there was a hitch somewhere in the arrangements, and it was transported to New York without having been seen, so far as we can learn, by any one. The machine was constructed here, and it was stated that no unemployed steam-power could be found in the city of sufficient capacity to test it. Dr. Hincks claims that his machine is no untried device, it being at the present time at work in England and Wales, in the mining districts, doing heavy work in tunnels at a distance of ten miles from the mountain stream, which is the source of power.

If the important end has been accomplished of changing mechanical energy over into electrical force, and then transmitting the same long distances by means of a wire, and again changing it to mechanical energy, so as to drive machinery, certainly results are reached of the highest consequence in industrial progress. It is claimed that this is accomplished with a loss of only twenty-five per cent. of the original power; or, to state the matter a little clearer, a turbine wheel affording one hundred horse-power at a stream can have seventy-five per cent. of the same delivered to shafting ten miles distant, the only medium of communication being a copper wire $\frac{1}{16}$ of an inch in diameter. A ten horse-power water-wheel, located anywhere on a farm or estate, could have more than seven tenths of its power brought to the farm buildings and dwelling, and used for lighting, warming, pumping, and all other uses for which it might be wanted. The development and practical results of a plan so magnificent as this will be watched with interest by every one.

1881. Electrician. July. 16.

ELECTRICITY AT THE ROYAL AGRICULTURAL SHOW AT DERBY.

(BY OUR SPECIAL CORRESPONDENT AT DERBY.)

It may be thought, and truly so, that few applications of electricity have been made in apparatus connected with agriculture. Still, it is now getting on for two years since a dynamo-electric machine was tried as a motor to actuate ploughs at Sermaize. So far as that experiment is concerned, there is no indication of its having made any deep impression by any apparatus to be seen at Derby.

The miscellaneous exhibits and those indirectly rather than those directly used for agricultural purposes indicate, perhaps, that the rubicon has been passed, and in years to come electrical appliances will be no unique things at these shows.

A large meed of praise will always be due to the Royal Agricultural Society from the pioneers of electric light enterprise, inasmuch as it has been under the auspices and incentive of this society that the portable and semi-portable engines so largely used for electric light purposes have been brought to the point of perfection they have obtained. All the eminent makers of these engines are represented at Derby, and it would be an invidious task to attempt to decide whose build of engine was the best where all are so excellent. There are engines by CLAYTON and SHUTTLEWORTH, by HORNSBY and SONS, by MARSHALL, SONS, and Co., by RANSOMES, HEAD, and Co., by ROBEY and Co., by RUSTON, PROCTOR, and Co., and so on, any one of which may be depended upon for design and workmanship. The designs of the various makers differ in minor details, each of which are supposed to present something superior to that of rival makers; but it is well known that, taken as a whole, the engines run one another very closely in any competition in which they may be engaged. It may not be out of place here to say that Messrs. Ransomes are engaged on an engine specially designed for electric light purposes, and we believe that this engine will be shown at the Paris Exhibition.

Mr. Turner, of St. Albans, exhibits a gas engine, which has been successfully tried with the Swan lamp at Lord Salisbury's. This engine, with the expenditure of 1 h.-p., kept alight 12 of Swan's lamps, but not at their full brilliancy. On reducing the lights to 8, however, the full effect was obtained.

We noticed that Messrs. Western and Co., of the Chaddiston Works, Derby, had two Siemens dynamo machines with which to drive some of the wood-working machinery exhibited. As we saw the arrangement, the driving machine was placed to drive a four-cutter moulding and planing machine, and we understood that the power obtained from the dynamo machine was from 4 to 5 h.-p. Messrs. Deakin, Parker, and Co., of Sandon Works, Salford, Lancaster, exhibit a specially designed 10 h.-p. stationary engine for electric light purposes. This engine is fitted with a modified Hartnell governor. It could not be shown in motion owing to an accident received during the transit by rail.

Thus we see that builders of engines are considering the special requirements of the electric light, and hence we may expect still further improvements in details. As usual, a telegraph office is open in the show yard.

PNEUMATIC TRANSMISSION OF POWER.

BY PROF. HENRY ROBINSON, C.E., LONDON.

The review in the issue of THE SANITARY ENGINEER for January 1, of "Isaac Shone's Pneumatic Sewerage System," may advantageously be followed by a reference to other data than those mentioned in the article.

In considering the special application of compressed air in the Shone appliances, it must be remembered that the efficiency of this motor depends on three factors; namely, (1) the air compressor; (2) the tubes transmitting the air under pressure; (3) the appliance worked by the compressed air.

In a paper which we read before the Institution of Civil Engineers in 1877, on the "Transmission of Power to Distances," we went at some length into the consideration of the useful effect obtained from compressed air, and the result showed that, as regards the first factor, about 50 per cent. of power was lost in the compressor. In other words, that a steam engine exerting a power of ten horses, at a steam pressure of about 40 lbs. to the inch, would lose one-half of that power in compressing the air and would transmit one-half. We also pointed out that the loss in transmission through great lengths of pipe was but trifling, when the joints were tight and the pipe surfaces smooth. One case was given of the application of compressed air to underground haulage in a colliery. The air was taken down shafts upwards of 300 yards in depth and conveyed a distance of 1,600 yards underground, with a *gain* of 2 lbs. per inch pressure, at the time that the air engines were working at the extremity of the line of air pipes. The experience gained in the Mont Cenis and in the St. Gothard tunnels shows that compressed air can be conveyed great distances with but little loss, depending on the size of the pipe conveying the power, compared with the volume of air to be conveyed in a given time, the friction varying as the square of the velocity.

The results of some practical experiments with compressed air, which we gave in the paper referred to, may be usefully repeated in the annexed table.

Having thus considered the proportion of useful effect which may be obtained from compressed air, we come to the third factor, namely, "the appliance worked by the compressed air." Here we think the apparatus used by Mr. Shone and termed the "ejector," is not quite understood by some, who have failed to see that the loss of power due to friction in working a rotary engine, or other compressed air appliance, is saved in the ejector, inasmuch as the air passes direct on to the fluid surface in the receiver, and its elastic force is not diminished by friction in passing through contracted orifices to a cylinder to actuate a piston. The temperature of the sewage that the compressed air acts upon is doubtless sufficiently high to prevent the refrigerating action, due to the sudden expansion which occurs after the air has passed through the cylinder of an air engine at a high pressure.

To form an opinion as to whether the advantages which are claimed for the pneumatic system of Shone are likely to be realized, it is necessary to bear in mind the conclusions which are deducible from the foregoing remarks. These conclusions may be briefly summarized thus: Where compressed air is employed at a pressure of about 4 or 5 atmospheres, and where, at its point of utilization it can be brought *directly* to do its work without loss of power in applying itself, then the most favorable conditions exist for the economic use of it as a motor, and these conditions appear to exist in the "ejector." It would be interesting to consider the application of gas or water from the town mains to work an appliance of this kind, as we think in many cases the utilization of existing mains to supply the power necessary to compress the air, might be better than creating an independent source of power and laying entirely new mains. This question, however, does not admit of being worked out in the compass of a short communication like this.

Before concluding, we would refer to a paper which has just been read before the Institution of Mechanical Engineers, by M. Achard, of Geneva, on the "various modes of transmitting power to a distance." Those who have studied this question will be familiar with the admirable articles of M. Achard, which appeared from 1874 to 1879 in the *Annales des Mines*. In the paper recently read, M. Achard states that the efficiency of the St. Gothard compressors has been approximately from 78 to 80 per cent. This greater co-efficient (which is estimated, for no experiments of a complete nature appear to have been made) is claimed to be owing to the injection of a very fine spray into the pump barrel of the compressor, whereby the water is brought into direct contact with the air to be cooled.

There is a wide field open for practical advancement in regard to the motors to which compressed air is applied, especially in the direction of avoiding the loss of power due to refrigeration by expansion, as well as the incomplete expansion in the motor.

The greatest progress in utilizing compressed air is exhibited in M. Mékarski's compressed air engine for tramways. The peculiar features of this appliance is that the air passes through a boiler with water at 248° Fahrenheit, before entering the cylinder of the engine. The air chambers on the locomotive are small and the air is stored in them at a high pressure. M. Achard states that in this engine the air goes through the boiler before passing the expander, so that if the temperature of the air in the boiler is 212°, and if the limiting pressure is 5 atmospheres, the gas which enters the engine will be a mixture of air and water vapor at 212°, and the pressure exerted will be due to a combination of 1 atmosphere, due to the vapor of water and 4 atmospheres due to the air.

ENGINEERING.

THE ELECTRICAL TRANSMISSION OF POWER.

M. CABANELLAS, who has given much consideration to the questions of production and distribution of energy by electricity, and who is the author of a system of automatic working of such a problem, has just communicated to the Academie des Sciences, of Paris, the theory in reference to the recent experiments made by M. Marcel Deprez, at Munich, on the electrical transmission of power, and to which reference has been made in these columns. M. Cabanellas' theory is as follows: "In the transmission of mechanical energy by means of two identical dynamo-electric machines, the ratio of the speeds does not express the value of the duty; the efficiency is equal to the product of the ratio of the speeds into the ratio of the fields."

Those who have had experience with dynamo-electric machines have remarked that for a given number of revolutions, per unit of time, of the generating machine, the maximum work is not obtained from the receiving machine when this is allowed to go at half the speed of the generating machine; but for a large number of types of machines the receiving machine should go at two-thirds the speed of the generator to obtain the maximum mechanical work. This fact, however, is in contradiction to a theory which is found in several scientific works, a theory which admits, explicitly or implicitly, the equality of the fields of the generator and receiver. But it must be granted by every one that from Lenz's law there follows the necessary reaction between the field and the moving current in each machine. The theory of M. Cabanellas takes exact account of all experimental results; his example shows how great this reaction may become with high speeds. M. Cabanellas' communication is moreover of great interest on account of the general method of reforming the electric elements which he applies to the particular case of the experiments of M. Marcel Deprez as to speeds, differences of potential, and current observed at Munich by the engineer who carried out the following experiments in accordance with the instructions of M. Marcel Deprez.* Now that very exact instruments for measuring currents and differences of potential are obtainable, the value observed by the easy method of M. Cabanellas for the total work given electrically to the generator has every reason for being much more exact than the value of the work obtained by interposing a transmission dynamometer between the mechanical source of power and the generating dynamo, since at a speed of 2200 revolutions per minute the error introduced in the traction, and thence in the work of one revolution, is multiplied thirty-six times in the determination of work per second. In this method M. Cabanellas has profited greatly by his former experiment on the increase of internal resistance of machines when running.

M. Cabanellas says:—In a series of studies on electrical machines, communicated to the Academie des Sciences, I have analysed the theoretical reasons which differentiate the reflex magnetic and electric elements of a machine according as this machine is worked mechanically to create electric currents, or is worked electrically to produce mechanical work. But No. 15 of vol. xcv. of the *Comptes Rendus* (October 9, 1882) has on page 633 a note from M. Marcel Deprez, the conclusions of which prove to me that in the interest of science and its applications it is indispensable to call attention to the results of the experiments of which I have spoken in a manner sufficiently concise for the figures to be followed. M. Marcel Deprez gives the results of an interesting experiment on the transmission of power to a great distance which he has made from Miesbach to Munich (fifty-seven kilometres of overhead telegraph line).

According to the note the receiving Gramme machine developed half a horse power measured on a brake at 1500 revolutions per minute, an identical Gramme generator at Miesbach running at 2200 revolutions. M. Marcel Deprez concludes, "That subtracting the passive resistances of every kind the ratio of the work reproduced at Munich to the work expended at Miesbach was as $\frac{1500}{2200}$ = more than 60 per cent." It was a departure from the above-quoted theory that caused M. Marcel Deprez in the preceding assertion to make an error which is very far from negligible, since I will show that from the results of this experiment the return instead of being about 60 per cent. was about 20 per cent., that is to say about one-third as much as the author of this experiment imagined. The above-mentioned note, besides the speeds of the machines and the work reproduced, gives only the resistances (in repose) of each of the two machines (470 ohms) and the total resistance (line wire and return) of the telegraphic circuit (950 ohms). There would not be in this the elements necessary for a numerical estimation, but I find the following series of figures in a recent publication which relates to the experiment at Munich, the *Bulletin de la Cie. Internationale des Telephones*: Power transmitted ½-horse power, resistance of each machine 460 ohms, resistance of line 1000 ohms, speed of generator 2100 revolutions, speed of receiver 1400 revolutions, difference of potential between the terminals of the generator 2400 volts, and between the terminals of the receiver 1600 volts, current 0.5 ampères. It will be seen that the two sources of information present in what they have in common an agreement sufficient to permit both to be taken as the base of an approximate calculation. It is reasonable to take without selection the figures of the most complete source which can be applied, although they are a little different from those of the experiment noted by M. Deprez. Let i = current, E the electromotive force of the generator, e that of the receiver, r the resistance of the generator when working, ρ that of the receiver, R that of the line, ϵ the difference of potential at the terminals of the generator, ϵ_1 the difference of potential at the terminals of the receiver, t the mechanical work reproduced per second (kilogramme-metre) t^1 the useless work of the receiver through rubbing of brushes and resistance of the air, g the acceleration of gravity. Neglecting at first the work done uselessly we have:

$$\epsilon_1 i = gt + i^2 \rho, \therefore \rho = \frac{\epsilon^1 i - gt}{i^2} = \frac{1600 \times 0.5 - 10 \times 37.5}{0.5^2}$$

$= 1700$ ohms, and $e = \epsilon_1 - i\rho = 1600 - 0.5 \times 1700 = \frac{gt}{i} = 750$ volts, but the resistance of the machine in repose is 460 ohms, and therefore the increase, for 1400 revolutions, is $1700 - 460 = 1240$ ohms. The increase for 2100 turns will be $\frac{1240 \times 2100}{1400}$ and hence for the generator $r = 460 + 1860 = 2320$ ohms, and $E = \epsilon + ri = 2100 + 2320 \times 0.5 = 3560$ volts, and therefore the return is

$$\frac{ei}{Ei} \text{ or } \frac{e}{E} = \frac{750}{3560} = 21.06 \text{ per cent.},$$

admitting that the current is not less at the receiver than at the generator, which would again lower the return. As verification

$$i = \frac{E - e}{r + R + \rho} = \frac{3560 - 750}{2320 + 1000 + 1700} = 0.55 \text{ ampères},$$

which would represent a loss of $\frac{1}{10}$ ampère = $\frac{1}{11}$ of the current in a total length of the wire of more than 100 kilometres. The positive and negative tensions vary gradually from a difference of 1200 to 800 volts with the potential of the earth. If it is wished to take account of the work t^1 reproduced uselessly in the receiver, the formula becomes

$$\epsilon_1 i = gt + gt^1 + i^2 \rho_{t_1}, \ \rho_{t^1} = \frac{\epsilon^1 i - g(t = t_1)}{i^2} \quad e_{t_1} = \epsilon_1 - i\rho_{t^1} = \frac{gt^1}{i},$$

and since

$$\rho_{t^1} = \rho_0 - \frac{gt^1}{i^2} \ \therefore e_{t^1} = \epsilon_1 - i\rho_0 = e_0,$$

which should be *à priori*. The useless work t^1 is easy to measure dynamically and even electrically by a method which I have communicated, and which has been inserted in the *Comptes Rendus*. In the absence of direct measurements we may estimate this useless consumption at one-tenth of the mechanical power reproduced by the receiver, *i.e.*, at 3.75 kilogramme-metres per second. The above formula gives us for $t = 37.5$ and t^1 3.75, $\rho = 1550$ ohms, $e = 750$ volts without any change, increase for 1400 turns = 1080,

$$r = 470 + \frac{1080 \times 2100}{1400} = 2090 \text{ ohms},$$

$$E = 2400 + 2090 \times 0.5 = 3145 \text{ volts},$$

$$\frac{e}{E} = \frac{750}{3145} = 21.77 \text{ per cent.}$$

Using the figures of M. Deprez's note or inert resistances it would be $i = \frac{3145 - 750}{1550 + 950 + 2090} = 0.58$ ampères. If in the numerator of f_1 we take account of the difference of potential lost through derivation on the line we find 0.51 ampères. We have judged it interesting to pass through all the details of the reconstruction of the electric elements, for we might have at once applied the formula

$$\text{Return} = \frac{gt}{\epsilon i + \frac{N}{n}\left[\epsilon_1 i - g(t + t_1)\right] - a i^2 \frac{N - n}{n}}$$

which applies if the line is perfectly insulated.

N n are the speeds of the generator and receiver, a is the resistance of the machine in repose at the strength of current i. But the formula

$$\text{Return} = \frac{gt}{\epsilon I + \frac{N}{M}\left[\epsilon_1 I - g(t + t^1_1)\right] - a_I I^2 \frac{N - M}{M}}$$

in which ϵ_I is the difference of potential between the terminals of the machine worked at a speed M by a current I, the work got out by the brake being t_1 and the useless work t^1, a_I being the resistance at rest under the strength of current I. The value of the current I at the generator being greater than I the value of the current at the receiver, approximately in this case where the line is imperfectly insulated the formula

$$\text{Return} = \frac{gt}{\epsilon I + I^2\left[\frac{N}{n}\left(\frac{\epsilon_1}{I}\right) - g\left(\frac{t + t^1}{I^2}\right) - a\frac{N - n}{n}\right]}$$

may be employed.

With the preceding approximate figures a calculation would give I = 0.65, which would reduce the return to less than 16 per cent. The kind of calculation which I have just made shows how useful and practical is the consideration of the increase of internal resistance of machines when working; also with what exactness it allows a great error to be rectified and of finding the return which a measure of the power expended at Miesbach will give, a measurement which is particularly easy and exact if, as has been remarked, the generator is driven by a separate gas engine. In fact, when M. Deprez admits that the return is equal to the ratio of the speeds he implicitly admits the equality of the magnetic fields of the generator and receiver, whereas through the reflex actions of which I have spoken (electric current in movement inducing magnetism) the generating field was more intense than the magnetic field, which the same current would develop with the armature in repose or turning with an open circuit, and the field of the receiver was less intense than this field not influenced, so that according to the figures given the field of the receiver in this experiment would be three times less intense than the magnetic field of the generator.

* M. Cabanellas has since acquired proof of the authenticity of these figures.

Engineering, December 1882.

ELECTRICAL TRANSMISSION OF POWER.

The first practical application in Scotland of the electrical transmission of power to a distance in everyday use has just been made at the works of the Railway and Electric Appliances Company, Polmadie, Glasgow, by Mr. Rankin Kennedy, electrician and engineer, formerly of Paisley and Kilmarnock. By means of two dynamo-electric machines, designed and made by him at the Polmadie Works, a power of from four to five horses is transmitted from the line of shafting of the turning and fitting shop of the works to the department occupied by the carpenters and pattern makers on the opposite side of the yard of the works. Thus transmitted, the power is used by those workmen for driving the large saws used in cutting their wood, and it is completely under their control. In this example of the electrical transmission of power there are used two of Kennedy's dynamos. One of them—the generator—which supplies the electricity—is placed on the floor of the turning shop of the works, and is driven by a belt from the line of shafting which drives all the machinery of the works. This generating machine runs all day, and from it two copper wires are led away to the carpenters' and pattern-makers' shop, where they are fixed and connected to the other dynamo, which, as in the former case, is also on the shop floor. This second dynamo is the motor which receives the electricity from the first, the shaft of the motor dynamo being caused to revolve at a speed of 600 revolutions per minute. A belt from the pulley on this shaft drives the saws when the current is turned by the switch handle.

MARCEL DEPREZ'S MUNICH EXPERIMENTS.

M. MARCEL DEPREZ has communicated to *L'Electricien* of December 1 a correction of the exaggerated deductions drawn from his Munich experiments, which in great part confirms the comments of M. Cabanellas, reproduced in our issue of the same date (page 517). M. du Moncel had announced in the *Temps* that M. Marcel Deprez had obtained an economical result at Munich of 60 per cent. of the power evolved at Miesbach. M. Deprez now explains that the figure of 60 per cent. refers only to the electric result, measured by the respective rates of motion of the generator at the Miesbach and the receiving instrument at Munich; but that the margin of power actually available for industrial purposes varied between 25 per cent. in the first experiment, when the generator was making 1500 revolutions per minute, and 30 per cent. in the second experiment, at 2000 revolutions per minute.

Engineering, Dec. 1888.

L'Electricien (Paris, October 15), publishes Captain Boulanger's second report to the Academy of Sciences on the Grenoble experiments, in which he treats of the electrical measurements and the distribution of the force transmitted. In an article commenting unfavourably upon M. Marcel Deprez's proceedings, it is pointed out that the only really scientifically tested observations as to the distribution of force, were made —not with power coming from Vizille, 8½ miles away, as was popularly supposed, but—with power generated by a machine at a short distance driven by a locomotive. Captain Boulanger is to present a third report, bringing the electrical figures into connexion with the dynamometrical results.

The same paper gives details (taken from the *Elektrotechnische Zeitschrift*) of the experiments in the electric lighting of trains, carried on upon the Vienna and Trieste Railway. The normal speed of the train selected is a little over 37 miles per hour, but between the stations of Gloggnitz and Mürzzuschlag, where it climbs the steep slopes of the Semmering, it is reduced to about 17 miles per hour, for the course of an hour and 40 minutes. This makes it exceedingly difficult to maintain an equable intensity in the light. The illumination is effected by a dynamo, driven by one of the axles, with which it is connected by bands. Before the machine is in motion, and during stoppages, the lighting is carried on by a current supplied by accumulators, which are recharged by the motion of the train itself, ready for the next interval in the action of the dynamo. Full details are given of the system, which is found to work well as long as the train travels on a level; but fails on the Semmering incline. Here the accumulators are unequal to furnish an adequate current, for which it would be necessary that they should each develop 18,000 kilogrammetres in the 100 minutes. On the contrary, a result of 18,000 kilogrammetres has only once been obtained from a single accumulator. These experiments, therefore, must still be considered as tentative.

obtained by Marcel Deprez in the electric transfer of power. The author describes these experiments at some length, quotes the favourable opinion expressed by M. Bert, and expresses the confidence that by this means Italy may derive great benefit from the utilisation of the mountain torrents descending from the Alps and the Apennines.

The second chapter discusses the general principles of electricity and magnetism, and is communicated by Prof. Ferrini, being, in fact, taken from his treatise, "Elettricita e Magnetismo." These principles are laid down in a number of detached paragraphs. We find here an account of the law of Coulomb, the experiments of Riess, Coulomb, and Hecker, the definition of the magnetic field as furnished by Sir W. Thomson, the theorem of Volta, the laws of Ohm, Lenz, and Jacobi, and an explanation of the standards of electric measurements.

The electric light, and the various forms of lamps, are the subjects of an extensive section by A. Casanova. This author gives a history of the electric light from its first discovery down to the present day. He describes the arrangements for the arc light, for incandescence, or glow lamps, the means of producing the necessary electric currents, such as the hydro-electric, the secondary, and the thermo-electric batteries. He then treats of electric induction and the principles of magneto-electric machines, several of which are described and shown in illustrations. The style of the figures is, however, not equal to that which we generally find in French, English, and American treatises. A. Casanova then passes on to an account of the distribution of the electric light, the system of M. Marcel Deprez taking a prominent place.

Some of the especial uses of the electric light are next described, as in lighthouses and in military operations. Here the writer notices its employment by the French in disembarking on the coast of Tunis, and adds a reflection on the manner in which science is made to minister to the caprices of human ambition. The introduction of the electric light for civil and industrial purposes is duly considered, and strong hopes are expressed of its future utility. We can scarcely see the reason for introducing a figure of the "solar motor" in this connection. This novel source of mechanical power may come into practical use in Australia and Africa, and may of course serve to drive dynamos; but in no part of Europe is the sun light sufficiently free from interruption.

The succeeding chapter, on electricity applied to the transmission of signals—in other words, to electro-telegraphy and telephony—is from the pen of P. Meardi.

Erminio Ferraris gives a preliminary account of an arrangement for electrolytic purposes, as in electro-metallurgy, galvano-plastics, &c. This chapter is short, and might easily have been rendered more instructive.

Dr. A. Baratieri treats of electricity in reference to the animal economy. In this chapter we find mention of the electricity of the gymnotus, and of the original experiment of Galvani, but there is nothing which can be called suggestive.

Dr. P. Schivardi discusses electro-therapeutics—a much abused subject.

The concluding chapter contains practical instructions for the application of electricity to household uses, and is of a somewhat promiscuous character. It includes the installation of the electric light without a motor, by means of the Gardino battery; the arrangement of electric bells, indicators, telephones, electric motors, gilding and silvering, the Mucci voltameter for medicinal purposes, and the determination of the poles in the battery.

There is little in this treatise to which direct exception can be taken as inaccurate. But the various sections are very unequal in their merit, and errors of arrangement are not wanting. Thus, in the section on animal electricity, we find much that belongs to the general elements of electrical science, and such "piper's news" as that "the atmospheric air is a body," or that "our globe is formed of a quantity of points, such as mountains, pyramids, obelisks, trees, church-towers." Very true, doubtless, but having little especial bearing upon the electric manifestations in animals.

The electric transfer of mechanical power, though referred to in the introductory section, is not made the subject of a distinct chapter.

THE EFFICIENCY OF SECONDARY GENERATORS.

WE observe that we are not alone in criticising the recent report given by Dr. Hopkinson on the Gaulard-Gibbs system of electrical distribution. M. Jules Sorcin writes as follows in the last number of *La Lumière Electrique:*

"In the calculations for percentage of efficiency we see two grave errors of a theoretical nature. The first is the violation of a well known arithmetical theorem; in the second, Dr. Hopkinson unduly applies Joule's law which, as is shown in all classical treatises, is not applicable to alternating currents.

Let us examine first the arithmetical error. We will designate by T the electric work furnished by the primary machine at the terminals; by l the electric work of the secondary generators, and by c the heat absorbed by the line. The individual return of the secondary generators is, by definition, the relation of the energy, l, which they give to that which they receive from the primary current. Now the energy which they receive is no other than that which is developed at the terminals of the primary machine, minus the caloric energy absorbed by the line, that is to say, $T - c$. The return is therefore expressed thus—

$$\frac{l}{T - c}$$

Now, Dr. Hopkinson does not proceed thus, he takes for the numerator of the fraction which expresses the rendering, the work of the secondary generators (9513 + 1875) augmented by the caloric work of the line (3630), that is to say, $l + c$, and for the denominator he takes, on the contrary, the work, T (16,710 watts) of the primary machine. The rendering thus defined would be equal to

$$\frac{l + c}{T},$$

which we may write

$$\frac{l + c}{T - c + c},$$

It is, therefore, the true expression of the rendering in which we have added the same number, c, to the numerator and denominator. Now, an elementary arithmetical theorem teaches that we increase the value of a fraction when we add the same number to the numerator and to the denominator.

The expression of Dr. Hopkinson is, therefore, always higher than the true rendering, and that in consequence of an error against the principles of arithmetic, the electric methods being accepted without discussion.

Let us see, now, how Dr. Hopkinson calculates the caloric work, c, absorbed by the line. For this he simply measures, by means of the electro-dynamometer, condemned at the beginning of his report, what we may call the intensity of the primary alternating current, he squares this intensity, and then applying Joule's law he multiplies by the resistance of the line, and finds 3,630 watts. Now, this mode of proceeding is inadmissible, since, as said above, it is impossible to draw any conclusion from the indications of the electro-dynamometer when it is applied to alternating currents. In order to be consistent with himself, Dr. Hopkinson ought to have applied to the line the method of M. Joubert.

We will point out, lastly, two important omissions.

62

duration. On this subject it is best to quote the certificate given by the Commission:—

"The dynamo machines were set in motion for the first time on Sept. 25th, at 7 p.m., and, according to the data of M. Datterer, the engineer appointed by the committee, the receiver placed at Munich revolved at the speed of 1,500 turns per minute, the brake, serving to measure the work, being loaded with 1·5 kilog.

"A series of accidents, due to the fact that the machines were constructed for laboratory experiments and not for practical work, arrested, after eight days, the progress which up to that time had been completely satisfactory. The circles surrounding the ring of one of them broke, consequently the wires of the ring of 0·4 mm. in diameter were damaged, and had to be insulated afresh. In the remote town of Miesbach these repairs were effected with great difficulty, and required, on the part of the assistants of M. Marcel Deprez, much patience and perseverance.

"On Oct. 9th and 10th, when the Commission of Investigation commenced its measurements, the greatest speed attained at Miesbach with the repaired machine was 1,600 revolutions per minute; the results were consequently much less favourable than they had been with the normal velocity of 2,000 revolutions per minute obtained at first.

"During a few moments only it was found possible to reach, during the measurements, the speed of 2,000 revolutions per minute, and quite at the beginning of the experiments one of the brushes of the machine became detached, which produced an extra current and destroyed the machine."

It will be seen from these extracts that the results were obtained under disadvantageous conditions.

They are not, moreover, perfectly exact, especially from the transmission dynamometer at Miesbach having been made for 15 horse-power, was ill adapted for the measurement of small forces.

The results were the following: work received 0·25 horse-power, electric return 38·9 per cent. The mechanical return was not measured, but it is estimated at about 30 per cent.

All this, doubtless, was but a beginning; but it differed so widely from the attempts previously made, that a great outcry was raised. There was a brisk, indeed a violent, discussion on the results, the procedures, and everything which seemed open to attack. However, as was said by M. Cornu in a report to the Institute, to which we shall have to return below:—"The very violence of the polemic which has arisen on this question suffices alone to show that the author, if he has not solved the problem, has at least approached it very closely."

It was impossible to stop on so open a road. Along with these public trials, laboratory experiments were also advancing, and M. Deprez succeeded in deciding on the construction of his permanent machines.

On account of particular circumstances, and of a special application which was projected at this time, it was not proposed to adapt the first machine to a distant transmission, but it was thought desirable to receive a quantity of work of practical importance.

A beginning was made with a single apparatus; prudence demanding that in novel regions we should advance only step by step. The machine was completed about the end of January, 1883; it was tried, at first, in the laboratory, and appeared to answer all expectations, but it was necessary to try it in a more practical manner, and on a real line.

A telegraphic line is not an easy thing to find. It is true one was urgently offered, but it was in Bavaria. As a sequel to the success of the first former experiment, the administration of Munich had urged upon M. Deprez to repeat it with the machines which he subsequently constructed. He might have accepted this offer, but it implied going to a distance, leaving France, and carrying his performances abroad. This did not please the inventor. Among the French telegraphic lines there are some which the Administration often devotes to experiments. But these are more especially reserved for telegraphy. Besides, it must be said that the Administration had an exaggerated fear of high tensions, and was reluctant to see them upon its lines. M. Deprez addressed himself, therefore, to the Companie du Nord. The engineer of the telegraphic service, M. E. Sartiaux, with great kindness, found a line which it was possible to withdraw from the general service for a few days. The engineers of the depots, MM. Delebecque and Sauvage, found in their work rooms a corner and driving gear; the working service and its engineer, M. J. Sartiaux, took the experiment under their charge, and occupied themselves with the details. In a word, the company showed a good will, for which M. Deprez is exceedingly grateful.

(To be continued.)

Disastrous Fire from an Electric Spark.—A telegram to the *Times* from Philadelphia, on April 4th, states that the steamer *Rebecca Everingham* caught fire on the Chattahoochie River, some 40 miles below Columbus, Georgia, about daylight on the previous morning, her cargo of cotton having been ignited by an electric-light spark. She was run ashore within a few minutes. The passengers had been roused, but some of them had to escape in their night-clothes. Of 30 persons, about 14 were killed and several others injured. The boat and cargo were a total loss.

63

A TRANSMISSION DYNAMOMETER.*

By Profs. W. E. Ayrton and John Perry.

We now come to a dynamometer of another character—viz., one for measuring the horse-power transmitted by a shaft to any machine. Much of the vagueness which exists as to the economy in electric lighting has arisen from there not having been any easy mode of measuring the power absorbed by the dynamo machine. In the very complete investigations of Mr. Schwendler, Dr. Hopkinson, and of others, transmission dynamometers were of course employed, but they were laboratory instruments. You do not find such transmission dynamometers fitted up, almost as a matter of course, in all cases between the engine and dynamo-electric machines; and one reason of this is because such transmission dynamometers are separate machines occupying space and liable to a considerable amount of oscillation when in use, requiring therefore the employment of a dash pot to damp the vibrations, &c. Feeling the inconvenience of all strap dynamometers, we have designed for the Guilds Laboratory at Finsbury a form of dynamometers which can be permanently attached to any shaft, and which will show at a glance the force being transmitted to any particular machine—not a dynamometer that is specially fitted up with a certain amount of trouble for some special investigation, but an apparatus that is always ready and always indicating, whether or not it is desired to make any use of its indications. And as there may be others like ourselves who feel the importance of having some such instrument, which shows at a glance to a manager of works the power absorbed by any machine, we have thought you might be interested in seeing the working drawing of the dynamometer now being constructed to transmit 10 horse-power.

B B[1], Fig. 1, is a loose pulley used to drive, by means of a strap, any machine, such as a dynamo-electric machine. F F[1] is a boss keyed on the shaft driven by the steam engine: this boss has four stout arms seen in Fig. 3, which are attached by four spiral springs to the rim of the loose pulley. If, then, the shaft be driven, and the motion of the loose pulley be resisted, by its having to drive, say, a dynamo-electric machine, the springs will be stretched, and the amount of such stretching, combined with the speed of rotation, will measure the power transmitted. So far we have been merely following General Morin. Now the question is, How are we to measure the stretching of the springs—that is, the twist the loose pulley and the keyed boss undergo relatively to one another? Such a twist of course produces a tangential motion which we desire to observe without stopping the machinery, and consequently without any system of unrolling paper and moving pencil, such as General Morin employed. We have sketched out various devices, in some of which the tangential motion was transformed into a radial motion, in others into an axial motion—that is, a motion along the shaft. For example, we employed the plan of attaching a cord to the rim of the loose pulley, and passing it over a little wheel on the arm of the keyed boss, its other end being attached to a little spiral spring which again was attached to the shaft. If, then, the loose pulley and keyed boss received a twist relatively to one another, the little spiral spring would obviously be more or less stretched according to the direction in which the twist was made. A bright bead then attached to any point on the radial portion of the cord would describe a larger or smaller visible circle as the shaft spun round, and the radius of such a circle would be a measure of the force transmitted. Another plan we employed was to carry this cord under a second little wheel on the shaft, and attach the end of the cord to a collar moving loosely along the shaft, the little spiral spring which previously was in the radial portion of the cord being now placed along the shaft, and having one of its ends attached to the collar, and the other to the shaft, so as to resist the motion of the collar produced by the pull of the cord. The force transmitted would then be measured by the position of this collar on the shaft. The method, however, shown in the diagram, of converting the tangential motion into a radial one, we consider preferable to the others just alluded to. H C is an arm, which, to combine considerable stiffness with lightness, is trussed in the plane of rotation as well as in a plane at right angles to this, as seen in the upper part of Fig. 3. This arm turns about C, a pivot on the rim of the loose pulley, and is moved by means of a link L L[1], attached at L by a pivot to the arm, and at L[1] by a pivot to the end of one spoke of the keyed boss, F F[1]. If now the loose pulley and the keyed boss receive an angular twist, the end, H, of the harm, to which a bright bead is attached, moves almost radially towards the shaft. The exact path of of the bead H is shown in Fig. 4 for different positions of C. Supposing, for example, we regard the keyed boss at rest, and that C moves to the point marked 1, then L will also move to 1 in the other curve, and H will move to 1 in the path it describes.

To measure, then the power transmitted by the engine to the machine, all that is necessary is to observe on a scale placed in a suitable position, the radius of the circle traced out by the bright bead H, and the number of rotations made per minute, both of which can, of course, be ascertained at any time without stopping the machinery.

An alternative arrangement which we employ with very stiff springs is to have a small pinion at L[1], which works into a short spur segment on the pulley. A very small relative angular motion of F F[1] and B B[1] produces in this case a great angular motion of the pinion, and therefore of a light arm which turns with the pinion, at the end of which there is a bright bead.

It will be observed that this form of transmission dynamometer is not only extremely convenient when the dynamo-electric machine is driven by a strap, but will be especially suitable when the machine is driven direct from the shaft of a fast speed engine, as, for example, one of Messrs. Brotherhood's three-cylinder engines. In such a case the shaft would really be in two portions, end to end, supported by suitable brackets; one keyed boss would be on one portion of the shaft, and an arrangement something like the loose pulley we have referred to would be on the other; but in this case it would, of course, be keyed to its portion of the shaft. Motion would be communicated from one portion of the shaft to the other through the spiral springs, and the extension optically observed in the manner we have described.

* A paper read before the Society of Telegraph Engineers.

SEPTEMBER 29, 1883.
THE DAILY NEWS,

ELECTRIC TRANSMISSION OF POWER AT THE VIENNA EXHIBITION.

Since the invention of the dynamo machine it has been possible to produce electricity much more economically than when we were compelled to use batteries, and the field of its application has been consequently enlarged. But even in the days of batteries there were many men who saw the convenience of using electricity as a motive power. One of the most interesting historical exhibits at Paris in 1881 was the fine series of electric motors designed by Froment. That skilful instrument maker actually worked the lathes in his workshop by electricity nearly 40 years ago. But a great advance has been made since that time. Perhaps the most remarkable fact in connection with the invention of the dynamo machine is that when a current is sent through its coils it becomes a powerful engine, and is the most economical means we possess of converting electricity into mechanical work. The most important installation for the transmission of motive power at this Exhibition is certainly the Electric Railway of Messrs. Siemens and Halske. This firm has now laid down so many of these lines that the conditions of working are fully developed. The current of electricity is generated by two large-sized dynamos. These are of the new type, called compound machines, in which the coils for magnetising the machines are so wound that a large or small quantity of electricity may be taken off for use in the circuit, and the electro-motive force does not vary. It is, perhaps, owing to this arrangement that there is so little sparking to be seen at the brushes of the machine. Those who were at the Paris Exhibition in 1881 will remember that the machines which there drove the tramway sent out showers of sparks whenever the speed of the car varied, and still more so when it started. No such objection can be raised to the present installation. The current is carried from the generators by wires to the rails upon which the cars run. The rails are not such as are used with tramways, but such as are used on railways. They are thoroughly well mounted on sleepers and are quite firm. This is the reason why this experiment is more successful than any which has been made by Messrs. Siemens. The successive rails are connected at the ends by strips of metal soldered to them. But at two level crossings over carriage roads the conductors are carried underground, and the rails are disconnected so as to prevent danger to horses and people. At these points the momentum of the cars carries them across. The difference of potential of the rails is 160 to 200 volts, which is not sufficient to be dangerous. The current is taken up by the wheels of the cars, and so transmitted to the dynamos which rotate under the influence of the current and communicate rotation to the wheels of the car by wire-rope gearing. The speed which is attained on this line is twenty miles an hour, the distance being one mile, and the engines and dynamos for generating the electricity being at one end. Two dynamos are used to generate the electricity, each using up about 25-horse power. The two large tram-cars are propelled together by the current thus generated, and they often carry a freight of nearly 100 persons, there being developed in each of the two motors about 12-horse power. It is pretty clear that when we can carry 100 persons a distance of twenty miles in an hour by an expenditure of five shillings' worth of coal, the problem of electrical railways has reached a practical stage. Close to Vienna, at Mödling, the same firm has just completed an electrical railway with cars something like the one just described, and one of which is exhibited in the Rotunda. It differs from it, however, in two points—the current is conveyed through overhead conductors as it was at Paris in 1881. This is necessary, because the railway goes along the main road. Again, in these cars the rotation of the dynamo is communicated to the wheels by means of toothed wheels. It is the first time that this has been tried. It may interest electricians to know that the line-resistance is 1.17 ohms, the resistance of the generator is 1.5, and that of the motor 2.28; it works with 400 volts and uses 30 to 40 ampères of current. The motor makes 750 turns a minute, going at ten miles an hour. The distance is a mile and three-quarters. There are curves of 3 metres radius and gradients of 1 in 60. On the car additional resistances of 2, 4, 8, 16, 32, 64 ohms can be inserted to diminish the speed, or the circuit may be broken. This same firm have in the Exhibition the plans of a system of metropolitan electric railways proposed for the town of Vienna. It will consist of a series of circuits in the centre of the town, all connected together by an outer circuit. The lines will be partly in tunnels and partly overhead. Within the last week the concession has been granted, and we may feel certain that the work will be done, and well done, by the firm which has already had so much experience in this kind of work. At the present time we have an electrical railway in Ireland. When we think of the successful installations at Lichtenfeld, in the mines of Saxony and La Perronière, at Charlottenburg, and other places, we see that it is time for England to come to the front, and to take the same position with regard to electricity which she has so long held with regard to steam.

The Electrical Power and Storage Company have attracted much attention by their boat and tricycle worked by accumulators. We in England have already seen such things, and no long description is necessary. The boat is driven by 78 cells actuating a dynamo machine, which is directly attached to the propeller shaft. By an ingenious arrangement of four brushes on the machine one pair or the other can be put in action by turning a handle, and so the motion is reversed. A switch is added by which 9 or 18 cells may be taken off to reduce the speed. The boat is said to go at about 12 knots. The tricycle has four cells in two boxes, one before and the other behind the axle. There is a switch to regulate the number of these boxes. We are told that it will run for an hour and a half. The accumulators used are the Faure-Sellon-Volckmar type. In their latest form these consist each of a glass cell containing 12 pairs of plates. Each plate is a foot square and about a quarter of an inch thick. A grating of lead is first cast, having spaces about a quarter of an inch square, which are filled with minium or litharge in the usual way. Here and there one of these holes has a piece of indiarubber instead of the lead salt. This is to keep the plates apart. Each plate has two ears at the top, which hang on the side of the glass cell. One ear is longer than the other. All the positive plates have the long ears on one side, and all the alternate negative plates on the other. The long ears on each side are connected by blocks of lead, through which a rod passes, and they are firmly screwed together by nuts on this rod. These are used for lighting purposes, and are supposed to be able to develop as much power as would result from two horse-power working for an hour. The cells on the boat and tricycle are smaller and of another construction; they are lighter but not so good. It is not too much to say that accumulators are still very far from being perfect. The plates wear out rapidly. They are irregular in their action. Some cells soon become worse than others, and as is well known the efficiency of a series of cells may be measured by that of the worst in the series. The committee of experiments, who by the way are now engaged upon their labours, have ten systems of accumulators to examine. I see no novelty deserving of notice. There is one kind in which the plates are concentric cylinders. The idea is that the expansion and contraction of the plates which takes place in charging and discharging will not tend to disintegrate them. Another one has plates two inches thick, but cast so as to look as if composed of horizontal laminæ. Without wishing to prejudge the question, it looks like an inferior form of Desmazures's accumulator. Another is a plain Planté secondary battery formed as he has always formed them, but I believe without the precautions which he has latterly adopted. Knowing as I did before coming here that the Austrians and South Germans had paid great attention to accumulators, it is a disappointment to see so little that is new or good.

The Gramme Company, which M. la Fontaine presides over, has brought here two gigantic machines of identical construction. Each has 12 field magnets, arranged in a circle, to the ends of which at one side the four pole pieces are attached, and the axis of the Gramme ring is central with the ring of field magnets. There are two pairs of brushes. The machine used as a generator uses up 60-horse power. The motor gives off 30-horse power; at least these are the figures which are given. The motor is used to pump water to the top of the water tower, which works a magnificent fountain in the centre of the Rotunda. There are 440 sections on the commutator of each machine. It generates an electro-motive force of 1,200 volts when doing 750 revolutions per minute. The same company exhibit the same form of machine in various sizes.

Messrs. Heilmann Ducommun exhibit the same workshop, with machines driven by electricity, as was shown at Paris in 1881. Other examples of transmission of power are shown by Siemens and Halske, Schuckert, Ganz and Co., and others. Schuckert has an ingenious breech-piece to which the brushes are attached, and which can be reversed in position so as to run the dynamo either as a generator or motor.

In conclusion, there is much here to interest those who study the transmission of power by electricity. There is no great novelty, but everywhere a distinct and marked advance in practice is to be seen since either the Paris or the Munich Exhibition.

The Engineering & Mining Journal

THE ELECTRICAL TRANSMISSION OF POWER.—*L'Electricité* gives the following account of M. Marcel Deprez's experiments at Grenoble, which we referred to in a recent note: The generator was placed in the cement-works of Messrs. Dumuyo & Co., at Vizille-Gare, where a turbine of 80 horse-power is in use. A double silicon bronze wire of ·002 meter diameter was fitted upon ordinary telegraph-poles along the road leading to Champ-Vizille, a third wire of brass serving for telephonic communication. The distance between the market-house at Grenoble and the Dumuyo works is eight miles 1230 yards. In the market-hall, a small workshop has been set up, in which are an endless band-saw, a circular saw, a printing-press, a Dumont centrifugal pump, etc., all of which are arranged around the receiver. This latter is the same that was used at Munich, but has been repaired. This time, M. Marcel Deprez has endeavored, if not to suppress, at least to greatly diminish, the effects of the distance to be traversed by increasing the electro-motive force, hoping to lessen the dangers of so doing by the insulation of the apparatus. He obtains this result by increasing the length of the wire on the machine, and diminishing its diameter. On the first evening, when the public was admitted by card, it was somewhat disappointed to see only the centrifugal pump at work. This raised 1200 liters of water, and formed a cascade which had a pretty effect. The speed of the generator at Vizille was about 600 revolutions, and it absorbed nearly 14 horse-power. On the Sunday, the committee appointed to make an official report verified the result at Grenoble to be 7 horse-power measured on a Prony brake; and at this time the speed of the generator at Vizille was 1257 revolutions, and it absorbed from 45 to 50 horse-power, which corresponds to a return of 15 per cent.

Transmission of Power by Electricity.—A novel application of the electrical transmission of power has lately been made at the Trafalgar collieries, Forest of Dean. The electrical arrangements were carried out by the Pyramid Electric Company, under the supervision of their managing director, Mr. A. Le Neve Foster. In this case, an electric motor is used to drive a pump in the underground workings. The pump is employed for pumping the drainage water from some of the deep workings to the bottom of the shaft, whence the ordinary steam-pumps raise it to the surface. The total vertical lift of the electric pump is 115 feet, while the length of pipes through which the water is forced is some 500 yards. A dynamo-machine is placed on the surface, for generating the current for working the motor, and is connected with it by wires led down the shaft and along the workings, a distance of some 500 yards. Messrs. Brain are satisfied with the result of the undertaking, and propose still further to extend the utilization of electricity as a motive power.

THE ENGINEERING AND MINING JOURNAL.

JULY 14, 1883.

THE TRANSMISSION OF POWER BY ELECTRICITY IN MINES.

The exigencies of special circumstances in the use of power in mines are often so peculiar that necessity forces engineers to adopt methods which above ground might be considered unwise. Work in inaccessible localities, danger of fire, inefficiency of ventilation, often make the carriage of steam through long lines of pipe practically impossible, and therefore hydraulic power, and more frequently still, compressed air, have found more frequent applications than above ground. A valuable addition to the number of methods of transmitting power over long distances has, of course, been hailed by mining engineers with much satisfaction, and they were among the first to turn transmission by electricity to account. Some time since, we submitted data gathered by work in a number of French mines, and through the publication of results by B. R. FÖRSTER, manager of the Royal Saxon collieries, we are in a position to add some details as to the experience gathered there.

Herr FÖRSTER has applied the electric transmission of power to two widely different cases. In the one, it was necessary to secure ventilation for the headings in a colliery at Zankerode. The plant consists of a Dolguruki rotary engine, running at a speed of 800 revolutions, directly coupled to a Siemens & Halske dynamo machine placed at a distance of 367·5 feet from the shaft. The conductor, a copper rod 0·275 inch in diameter, is carried down the shaft to a depth of 856·3 feet, and from there to the fan, 1335·4 feet, a total distance of 2559·2 feet. The second machine, of the same type, mounted in the mine, is connected with the fan by belting, the fan being of the well-known Schiele type, with a 3·2-foot wheel, capable, according to the statements of the builders, of furnishing, at a speed of 500 revolutions, 6361 cubic feet of air at a pressure of 0·70 inch, and at an expenditure of power of 1½ horse-power. A series of tests were conducted above ground, with the whole plant complete, but with a length of conductor of only 160 feet. It was found that the engine delivered to the dynamo-electric machine producing the current 2·56 horse-power, of which 1·4 horse-power was converted into work in the receiving dynamo-electric machine, thus showing an efficiency, with a circuit of 160 feet, of 54·3 per cent. The dynamo was then running at a speed of 481 revolutions, which was reduced to 418 revolutions when the plant was in full operation, so that the efficiency of the transmission was reduced by 3·0 per cent in addition, thus carrying it down to very nearly 50 per cent. The fan, when the driving dynamo was running at 800 revolutions, was making 361 revolutions per minute, delivering 7000 cubic feet into the air. The cost of the entire plant was low, and it is reported to have worked efficiently for many months since its construction.

The second case of a successful application of the transmission of power by electricity is quoted by Herr FÖRSTER, who arranged the electric railroad in one of the main cross-cuts of the Oppel colliery at Zankerode. The cross-cut is 2362 feet long, and is the outlet for the coal mined in the vein, the quantity delivered to it being 600 mine cars per day of 16 hours, each car containing 1017 pounds of coal, and weighing loaded 1591 pounds. We can not enter into details of the construction of the plant. It resembles in many points the design generally adopted by SIEMENS. In practice, a train of fifteen cars is moved at a speed of from 7·4 to 9·8 feet a second, the steam-engine at the mouth of the shaft making from 225 to 250 revolutions during the run, lasting from 3¼ to 4¼ minutes, through the 2034 feet of cross-cut. When the steam-engine was doing this amount of work, it delivered, according to brake trials made, 11·2 horse-power. The locomotive was at the same time developing 4·18 horse-power, or, assuming the friction of the gearing of the locomotive to have occasioned a loss of 25 per cent, the power actually transmitted by the electric current to the locomotive was 5·22 horse-power, or 46·6 per cent. The consumption of steam, with a pressure of 65 pounds, is estimated at 45·6 cubic feet per round trip of 15 cars. Herr FÖRSTER gives a statement of cost in which he shows that, making an allowance of 15 per cent of the cost of plant annually for wear and tear and sinking fund, it costs per car of coal hauled 3·01 pfennige with the electric road, 3·71 pfennige with horses, and 6·2 with men, when hauling 600 cars per day. When the capacity is increased to 800 cars per day, the cost for the electric road is reduced to 2·70 pfennige, while the others are not sensibly affected.

These two examples, we believe, furnish ample proof of the fact that there are probably many cases in which the transmission of power by electricity would pay well, notwithstanding the fact that the loss may be roughly placed at 50 per cent for moderate distances. This is particularly so where fuel is cheap, or where high heads of water are available, as in many of our mining districts, so that turbines running at a high speed can be used to drive the dynamo machines. There is only one point in connection with the electric railroad which needs attention. It seems difficult and dangerous to stop the trains suddenly, so that the engineer has not that absolute control over the locomotive which, is desirable, even in underground roads.

M. Desprez has lately attacked the problem of transmitting, by means of an electric current, the motion of a motor A to a receiver at some distance B, as a rigid axis between the two would do, so that the angular velocity of B should be always equal in amount and sign to that of A. (The particular case was that of getting within a railway carriage a rotation identical with that of the motor wheels of the locomotive.) On the shaft of the transmitter A are fixed two commutators, each of which reverses the current that traverses it twice each turn; but the positions of the shaft corresponding to these inversions do not coincide; they follow each other at intervals of a quarter of a turn. The receiver consists of a permanent magnet or electro-magnet, between the branches of which are two straight electro-magnets, capable of rotating round an axis which coincides with that of the magnet. The currents sent through these electro-magnets from the shaft A produce the desired effect. This apparatus (it is noted) effects the transmission of work of a motor from one point to another *with conservation of the angular velocity* (which has not been realized in any electric motor hitherto used), the latter varying from 0 to 2,400 turns per minute. The alternating currents required may be generated by a magneto-electric machine. Again, any motion may be considered as the resultant of two movements of rotation; hence this apparatus, with a simple mechanism added, would serve for transmission of a motion of drawing, or writing.

IRON

MARCH 21, 1884.

THE TRANSPORT OF GOODS BY ELECTRICITY.—Professor Fleeming Jenkin, of Edinburgh, delivered a lecture on "Telpherage, or the Automatic Transport of Goods by Electrical Means," before the Glasgow Science Lectures Association on March 6. The chairman (Sir William Thomson), in introducing the lecturer, said that Professor Jenkin proposed to apply electricity in an altogether novel way, and one which was most interesting to this society. The professor had long been interested in engineering subjects, and his latest idea was to show how goods, parcels, and possibly passengers, were to be carried overhead through the same power as that which had done so much under the sea in the shape of the submarine cable. Professor Jenkin, at the commencement of his lecture, explained the origin of the word "telpherage," and said that it was derived from two Greek roots, and meant the "far carrying." It was the old story of a person hanging a pair of boots on a telegraph wire and expecting that they would be sent to a distant friend that had set him thinking about the possibility of really carrying the idea into practical use. By means of a model railway, built upon the platform on raised supports, wires stretched from point to point taking the place of fixed rails, he proceeded to explain the system upon which he would carry out his invention on a larger scale. Two model trains were set in motion and successfully made a round of the circular railway, the motors working admirably. The professor then explained the system under which the motors worked, and how the electricity was utilised in carrying along the load put on the suspended wire railway. In working out this idea he had simply made use of the perfectly well-ascertained electric laws which had been developed chiefly in connection with electric lighting. Some ten years ago, had this idea occurred to him he should have put it entirely to one side, as at that time there was too much to be done in respect to electricity to make it practicable. But one thing led to another, and electric lighting had developed dynamos to such an extent that sufficient power had been obtained to use it as a motor, and it was the great development of that power which had led him to make the experiments the results of which he was about to explain. He then gave a description of the "line," and referred to the difficulties he had experienced in getting up a proper kind of "locomotive." He had aimed at conquering gradients that no steam locomotive could look at. It was necessary to avoid in electric locomotives all loss of power by friction. It took curves easily, and without any kind of friction whatever, and there was hardly any possibility of the trucks being thrown off the line. A model train was next run along a model railway terminating in a series of octagon circles, and the trucks took the curves freely and without a hitch. He now came to the economical question, to see how far from being a mere toy the idea could be developed into a practical working machine able to do the work required by the manufacturers of the country. The lines were not intended to compete with the railways, but rather to act as feeders to them by collecting goods throughout districts, carrying them to the stations, where they would be put into the trucks. This would have a great influence upon the railway traffic. The class of line he would put up with posts and rods ought not to cost more than £500 per mile. For engine-power for a 25 mile line he would put down £1,600 per annum. In concluding, Professor Jenkin said he did not propose to touch upon all the matters connected with the possible development of his scheme. He would simply leave his hearers with the impression that the whole contrivance was what he might simply call an electric horse and cart. Mr. Renny-Watson, in proposing a vote of thanks to the lecturer, said that the system was one that he hoped to see applied to the underground railways, and so do away with the smoke nuisance that troubled passengers by these lines.

Iron – Feb. 3, 1882

where a dividing box was placed, into which they were fixed. From this box five pairs of wires were conveyed, one pair to a circuit of six Edison lights, and others to dividing boxes, whence wires led to other smaller or larger circuits of similar lights. Whether there were one or two or five or six lights on the circuit, the light was the same. It will be seen from the above that the invention is simple, and that it is one of a very common-sense character, and that our previous statements were fully borne out by the experiments just witnessed. To say the least of it, Mr. Rogers' plan no doubt solves some of the greatest difficulties in the way of the general adoption of electric lighting, especially for domestic purposes, and at the same time leads to greater economy in its use. Moreover, though his system of division is entirely different from that of any other system, yet every system of electric lighting may be adaped to it.

by dividing boxes, which are reservoirs of electricity, and from these reservoirs the divisions of the current are drawn as the electricity is required. The divider consists of two or more copper spheres, one placed inside the other, which receive and distribute the electric current by means of wires arranged for the purpose. It appears probable that these spheres, from their construction, may to some

THE TRANSMISSION OF POWER BY ELECTRICITY.

ALTHOUGH a great deal has been talked and written about the transmission of power by electricity, very little has been done beyond a few desultory experiments. There is Sir W. Armstrong's installation of the electric light at his seat in Northumberland, the Siemens, and other electric railways, M. Menier's experiment in ploughing at Sermaize, and sundry other applications on the small scale; but no one has yet come forward with any definite proposition to utilise the Falls of Niagara or to seize upon the enormous water power running to waste in the gorge of the Severn, which latter we have been assured would be sufficient to supply all the factories in England. The subject has been fairly placed before capitalists by Sir W. Thomson, Sir W. Armstrong, Prof. S. P. Thompson, and others in this country, and includes a proposal to transmit the energy of coal to the metropolis and elsewhere by wire instead of forwarding the coals themselves by railway. There seems to be no doubt in the minds of those who suggested the transmission of power by electricity that 50 per cent. of the energy expended at the source of the power could be delivered at long distances, and it will therefore follow that even in the case of coal, if it is consumed at the pit's mouth, the power can be transmitted in the shape of electricity with economy. In the cases of water and wind, sources of energy which cost nothing first hand, there is only the interest on the sum expended in machinery necessary to utilise them to reckon as the prime cost of the motive power, and if that machinery can be constructed in an inexpensive manner, it is time that some experiments on a large scale were made. If it is possible to utilise the tidal flow of the Severn, Bristol could easily find a use for a portion of the electrically transmitted power, and both Birmingham and London are not so far off that the cost of the leading wires would prevent the use of energy so cheaply obtained. At any rate, assuming that the machines worked by the water of the Severn were placed somewhere in the neighbourhood of Avonmouth, the cost of copper rods to lead the current to Bristol would not be very heavy, and there are a sufficient number of factories and workshops in that city and its environs to fairly test the question on the large scale. It is not impossible that capitalists and others who might be inclined to take the matter in hand are waiting to see how Mr. Edison succeeds in his attempt to supply a whole district in New York with current for both power and light. His main leads are stout copper rods of about half-moon section, carefully cemented into iron tubes with an insulating material, and it is obvious that much of the success of the installation will depend upon the behaviour of the latter, for leakage of current would very seriously increase the cost, and if excessive would practically render the system inefficient. If any difficulty is experienced in keeping up the insulation where the leads are laid beneath the footwalks of cities, it is tolerably obvious that it will not be easy to keep the "wires" in proper electrical condition when they stretch over many miles of country. In his recent address, as President of the British Association, Dr. Siemens took 50 per cent. as a safe estimate of the amount of energy that could be transmitted by electrical means; and he pointed out that as large steam-engines work on a consumption of 2lb. of coal per horse-power, whereas small ones use 5lb., there is an economy which, with other advantages, balances the loss of energy in the electric system. As a matter of fact, calculations show that between producing the current in one machine and reconverting it into mechanical effect by means of another, the loss should not be more than 20 per cent., and some carefully-conducted experiments made at the Stevens Institute of Technology, Hoboken, N.J., give a smaller loss than that. These experiments were made by G. and W. E. Gibbs, and form a thesis, an abstract of which we find in *Van Nostrand's Magazine*. The machines used were of Weston's latest pattern, the generator being a "fifty light incandescent machine," and the motor a "forty light" of the same construction—viz., the "derived field" type, the field-magnets being wound with comparatively fine wire, so that their resistance was about 500 times the resistance of the armature. The dynamometer used for measuring the power transmitted by the engine to the generating dynamo was one of the Kent type, built at the Stevens Institute, and was carefully standardised for the purpose of these experiments. The bearings of the armature were "assumed" to absorb 2·5 per cent. in friction, as no suitable apparatus were available for determining it experimentally; but there is no reason for thinking it more, while it is probable that it was less. In testing the efficiency of the generator, the current was carried by iron wire resistances running across the room from side to side in the open air, so that the heat was rapidly conducted away. A switch was so arranged that the generator could be instantly thrown out of circuit, and the resistance of the line measured within five seconds by a Thomson high-resistance galvanometer. In determining the electrical energy developed by this method a calorimeter was used in circuit with the iron wire resistance. The actual figures show that the energy applied to revolve the armature was 112,440 foot-pounds per minute, and the total electrical energy developed in the circuit, 108,446·28 foot-pounds, so that the efficiency of the generator was ·963: that is, 96·3 per cent. of the power applied to the armature appeared in the circuit and magnet-coils. Deducting the electrical energy consumed in the field-circuit and the internal work, the machine gave a commercial efficiency of ·860, or 86·0 per cent. of the energy actually applied to the armature pulley. Tests by measurement of the E.M.F. and R. gave efficiency as ·975 and commercial efficiency as ·861. In determining the efficiency of the motor as a machine for converting electrical energy into mechanical, the two were connected by heavy copper rods so as to reduce the loss of energy in the line to a minimum. A Prony brake was applied to the pulley of the motor, and the pressure of its arm on a platform scale gave the measurements directly. The brake was kept cool by a stream of water, so that runs of any desired length of time could be made. The machines used were, however, so large that they could not be worked up to their full capacity with the appliances at hand, but the results obtained are interesting and trustworthy. A number of trials, made at various speeds, showed that the motor was well adapted to act as a machine for converting electrical energy into mechanical power; but the combination of the generator and the motor was not altogether satisfactory, the highest efficiency being ·537. The generator in this case absorbed 197,200 foot-pounds of energy, and the motor did 115,866 foot-pounds of work. The loads, and the difference of speed of the two machines, were varied by means of the brake, the generator being kept at one steady rate during thirteen experiments, but the best result was that given above. The authors of the thesis, referring to the low percentage of the efficiency when the generator and motor are coupled, point out that the cause is obvious. By one of the fundamental laws of electricity the work done in any portion of an electric circuit is directly proportional to its resistance; and in the case of the two machines upon which they experimented the resistance of each was very low and equal when coupled, while that of the line was practically *nil*. Under these conditions nearly half the work must necessarily be done in the generator; but in order to increase the efficiency of the combination, more work proportionately must be done in the motor and less in the generator. In the case of a single motor they propose to reduce the resistance of the generator armature, and raise that of the armature of the motor, so as to cause nearly all the work to be done in the motor. If several motors were supplied with current from a single generator they propose to arrange them in multiple arc, so that when coupled up the total resistance would be the same as that of a single motor doing the combined work of all. If the proper ratio of resistance is determined by experiment, the authors think there is no reason why the continued efficiency should fall short of 80 per cent. If such a result as that can be obtained at, say, 50 miles from the prime mover, there is hope for the general adoption of transmission of power by electricity; but at present nothing of the kind has been done, the extreme limit of any experimental transmission being well within 10 miles.

disc also carries at its centre a cone projecting upwards and entering the mouth of the pipe leading to the burner. The gas enters the bottom of the collapsible vessel from which it can issue into the casing through the hole or holes in the disc, and from the casing it passes to the burners. According as the pressure of the gas is greater or less the collapsible vessel becomes more or less distended so that the cone on its disc throttles more or less the passage leading to the burners.

The sectional figure annexed shows the general construction of the burner. A is the gas chamber connected direct to the supply, and rising from it are the three concentric rings of tubes B. Surrounding the outermost ring is a casing C fixed to the chamber A, but having around its lower part a number of slots through which the air enters freely. The second ring of tubes is surrounded at their upper parts only by another casing N which terminates at the top of the tubes in a notched air deflector. A third casing T serves as a gallery to support the chimney and to admit a further supply of air for cooling the glass. A notched air deflector E is carried on a central stem and is fixed a short distance above the tops of the inner ring of tubes. The tubes are so graduated in size that the inner give the shortest flames, the object being to insure the termination of all the flames at about the same level. The air entering through the openings in the lower part of casing C passes between the tubes of the several rings and rises up in a more or less uniformly distributed manner, as does also that entering the lower ends of the casing N and being caused by the several notched deflectors to impinge in divided streams upon the ignited gas jets issuing from the tubes, produces an intensely luminous flame. All the metal parts of the burner are in solid connection with each other, so as to prevent the injurious overheating of certain parts, by causing the heat to be more or less uniformly distributed by perfect conduction, which heat is then in great measure taken up by the entering air, thereby also increasing the luminosity of the flame. In consequence of the good conduction of the heat from all parts of the burner, the use of porcelain or steatite for the mouths of the burners can be dispensed with, but the central deflector E is by preference made of porcelain in order to act as a reflecting surface for the light. The heat conducting powers of the metal gas tubes B and the comparatively large issue orifices effectually prevent the deposit of solid carbon within the tubes, and as the air becomes heated by contact with the external surfaces of these, an upward draught is produced whereby a comparatively short glass chimney is rendered applicable.

PERRY'S METHOD OF DISTRIBUTING ELECTRICAL ENERGY.

A METHOD of distributing electrical energy has, together with the apparatus necessary for carrying it out, been recently patented by Mr. John Perry, the professor of mechanical engineering at the Finsbury College of the City and Guilds Institute. In any scheme for distributing electrical energy, it is of the first importance to so arrange the wires, &c., that any consumer may use the current for the purpose of illumination, or for motive power, just as he pleases, without being interfered with in any way by the fact that other consumers have turned off their lights or turned on their machines. Various methods have been suggested for effecting the constant and unvarying distribution of electricity; but the method preferred by Prof. Perry consists in combining with the dynamo-machine, one or more magneto-electric machines or other form of electrical machine or battery which will produce in a circuit an electromotive force which is constant and independent of any other electromotive forces in the same circuit. First: When the consumers' wires are arranged in parallel arc, it is usual to employ a "series" dynamo, and in that case is introduced into the main circuit a magneto-electric machine or battery producing a constant electromotive force equal to the electromotive force which ought to exist between the supply cable of any consumer and the return cable or earth. The dynamo-machines ought to get constant speeds, being driven by engines with good governors, and these speeds ought to be what have been termed the critical speeds. That is, the speed of each dynamo machine ought to be such that the electromotive force created in it by its motion ought to be proportional to the current circulating in the coils of its field-magnets. In scientific language the intensity of the magnetic field in which the armature rotates ought to be proportional to the magnetising current. It is evident that one large dynamo-machine is preferable to two or more smaller ones in such a case, and it will be better to employ larger field-magnets than are usual in dynamo-machines; but to use the dynamo-machines at present in use will not introduce much discrepancy from the conditions required. As an example, if there is only one dynamo-machine, and if the resistance of the main cable, return cable, and machines, in fact of that part of the total circuit which is supposed to be constant be, let us suppose, 3 ohms, then we find that the dynamo-machine ought to be run at such a speed that the electromotive force in volts produced in its moving parts is three times the current in ampères which flows through the field-magnets; consequently, this speed can readily be found by experiment. Suppose the constant electromotive force of the magneto-machine to be 50 volts; its resistance 0·3 ohm, and the resistance of the dynamo-machine and of the other unchanging parts of the circuit 2·7 ohms, and suppose that the speed is that at which the electromotive force produced by the rotating armature of the dynamo is 3 times the current. Now let there be a consumer's resistance of 2 ohms, the total resistance is 5 ohms. Evidently the electromotive force produced in the dynamo is 75 volts, and the total electromotive force in the circuit is, therefore, 125 volts, and, as the total resistance is 5 ohms, the current is 25 ampères, giving an electromotive force of 50 volts between the ends of the consumers' part of the circuit. Now if the consumers' resistance increases to, say, 12 ohms by some of the consumers ceasing to use their circuits, there is an instantaneous alteration of the electromotive force produced in the dynamo to 12½ volts or 62½ volts in the whole circuit, and 62½ divided by 15 gives 4 1-6th ampères; and this means 4 1-6th multiplied by 12 or 50 volts as before between the ends of the consumers' part of the circuit. Instead of using the dynamo-machine of the ordinary type, that is with its field-magnets forming part of the main circuit, it is sometimes used in the form where the field-magnets act as a shunt. When using a dynamo-machine of the shunted field-magnet type, it is preferred to place the magneto-machine or other source of constant electromotive force in a part of the circuit which is quite outside the machine; that is in the main circuit, so that the current passing through it is that which goes to the supply cable. The speed may be determined, which will produce the desired result. Second: So far, we have considered the lamps or machines which are supplied with electricity to be "in parallel arc"; when, however, the lamps or machines to which electricity is given are "in series,"—that is when the same current is to go through them all, what we effect is that they shall all receive the same current of electricity, however the resistance of one or more of them may vary. This is attained by using, instead of an ordinary "series" dynamo-electric machine—one or more dynamo-machines constructed so that their field-magnets are a shunt between their brushes, or the binding screws connected with their brushes, combined with one or more magneto electric machines or some other form of electrical machine or battery which will produce an independent electromotive force. For simplicity, take the case of one dynamo-machine and one magneto-machine. Let the shunt part of the dynamo be called M, whether it contains merely the wire of its own magnets, or has the magneto-machine inserted in it. Let the part of the dynamo which contains the wire of the revolving armature be called A, and let us be able to insert a magneto-machine in this portion of the circuit if we please. Now the two ends of A and the two ends of M are the same, and these may be called the binding screws of the machine. If these binding screws are joined to the two ends of any external wire or cable or system of lamps in series, which we may call the external circuit being really the part of the whole circuit which is external to the machine, then if we introduce a magneto-electric machine in the part A or in the part M, or if we have a magneto-machine in A and another in M we can, by giving a certain constant speed to the machine, deliver a constant current of electricity through the external circuit, however the resistance of that circuit may vary. The constant current we find to be that which the magneto-machine or machines would produce in a circuit whose total resistance is equal to the resistance of A. Thus if a magneto-machine or other constant source of electromotive force producing a constant electromotive force of 100 volts is inserted in A, and if its internal resistance is 0·3 ohm, and if another magneto-machine whose constant electromotive force is 160 volts and internal resistance is 2 ohms be inserted in M, and if the resistance of the revolving part of the dynamo (from brush to brush if it were working in the ordinary way) be 0·5 ohm, then when joined up to an external circuit in the manner described, and run at constant speed, the current in the external circuit will be the sum of 100 and 100 divided by the sum of 0·5 and 0·3, or 325 ampères, or else it will be the difference of 100 and 100 divided by the sum of 0·5 and 0·3, or 75 ampères; the latter case being one in which the magneto-machines oppose each others' actions. But in either case the current in the external circuit will not alter although its resistance be altered. The constant speed at which the Dynamo-machine should be run may be determined by experiment and calculation. The speed should be such that the electromotive force produced in the armature by rotation is equal to the current in M which includes the field-magnets multiplied into the sum of the resistances of A and of M. It is possible by running even an ordinary Gramme machine at lower speeds than usual to get the electromotive force produced in the armature to be proportional to the current in the field-magnets. As to the distribution of electrical power to persons who consume it in parallel arc, and distribution of electrical power to lamps or machines which are joined up in series in one circuit, the dynamo-machine must be run at a constant speed. Suppose it is found by calculation that it is necessary to run a dynamo-machine at such a speed that the electromotive force in volts produced in the revolving armature is equal to the ampères of current passing in the field-magnets multiplied into 2 ohms. Make an experiment letting a current of 20 ampères pass through your field-magnets, and let them be disconnected from the armature circuit. Revolve your armature at a speed of, say, 200 revolutions per minute, and let us suppose that you find that an electromotive force of 100 volts is produced by the rotation. If the machine is a suitable one for your purpose, so that the proportionality of electromotive force to the product of field-magnet current and number of revolutions holds, then the constant speed required is 2 multiplied by 200 and by 20, and divided by 100, or 80 revolutions per minute. In the process of electroplating, we have exactly the same conditions as there are in the distribution of electrical power when the consumers' connections are in parallel arc; that is, in an electroplating bath there ought to be maintained a constant difference of electrical potentials between the two sides of the bath however few or many objects may be undergoing the electroplating process. Instead, therefore, of employing a single dynamo-machine, which is the common plan at present, Prof. Perry employs in the circuit one or more magneto electric or other electrical machines or batteries, which will produce a constant independent electromotive force, as well as one or more dynamo-machines. In the process of charging accumulators the current that should pass through each cell depends on the size and weight of the accumulator, but not at all on the number of accumulators to be charged. When it is desired to vary at will the number of accumulators to be charged, we arrange them partly in series and partly in parallel circuit, and use either the first or second system of supplying constant electric energy to each accumulator. With the first arrangement, when it is desired to increase or diminish the number of accumulators charging, we increase or diminish the number in parallel circuit, leaving the total number in series unaltered. On the other hand, when the second arrangement for supplying constant electric energy to each accumulator is employed, and it is desired to increase or diminish the number of charging, we increase or diminish

A TRANSMISSION DYNAMOMETER.*

By Profs. W. E. Ayrton and John Perry.

WE now come to a dynamometer of another character—viz., one for measuring the horse-power transmitted by a shaft to any machine. Much of the vagueness which exists as to the economy in electric lighting has arisen from there not having been any easy mode of measuring the power absorbed by the dynamo machine. In the very complete investigations of Mr. Schwendler, Dr. Hopkinson, and of others, transmission dynamometers were of course employed, but they were laboratory instruments. You do not find such transmission dynamometers fitted up, almost as a matter of course, in all cases between the engine and dynamo-electric machines; and one reason of this is because such transmission dynamometers are separate machines occupying space and liable to a considerable amount of oscillation when in use, requiring therefore the employment of a dash pot to damp the vibrations, &c. Feeling the inconvenience of all strap dynamometers, we have designed for the Guilds Laboratory at Finsbury a form of dynamometers which can be permanently attached to any shaft, and which will show at a glance the force being transmitted to any particular machine—not a dynamometer that is specially fitted up with a certain amount of trouble for some special investigation, but an apparatus that is always ready and always indicating, whether or not it is desired to make any use of its indications. And as there may be others like ourselves who feel the importance of having some such instrument, which shows at a glance to a manager of works the power absorbed by any machine, we have thought you might be interested in seeing the working drawing of the dynamometer now being constructed to transmit 10 horse-power.

B B', Fig. 1, is a loose pulley used to drive, by means of a strap, any machine, such as a dynamo-electric machine. F F' is a boss keyed on the shaft driven by the steam engine: this boss has four stout arms seen in Fig. 3, which are attached by four spiral springs to the rim of the loose pulley. If, then, the shaft be driven, and the motion of the loose pulley be resisted, by its having to drive, say, a dynamo-electric machine, the springs will be stretched, and the amount of such stretching, combined with the speed of rotation, will measure the power transmitted. So far we have been merely following General Morin. Now the question is, How are we to measure the stretching of the springs—that is, the twist the loose pulley and the keyed boss undergo relatively to one another? Such a twist of course produces a tangential motion which we desire to observe without stopping the machinery, and consequently without any system of unrolling paper and moving pencil, such as General Morin employed. We have sketched out various devices, in some of which the tangential motion was transferred into a radial motion, in others into an axial motion—that is, a motion along the shaft. For example, we employed the plan of attaching a cord to the rim of the loose pulley, and passing it over a little wheel on the arm of the keyed boss, its other end being attached to a little spiral spring which again was attached to the shaft. If, then, the loose pulley and keyed boss received a twist relatively to one another, the little spiral spring would obviously be more or less stretched according to the direction in which the twist was made. A bright bead then attached to any point on the radial portion of the cord would describe a larger or smaller visible circle as the shaft spun round, and the radius of such a circle would be a measure of the force transmitted. Another plan we employed was to carry this cord under a second little wheel on the shaft, and attach the end of the cord to a collar moving loosely along the shaft, the little spiral spring which previously was in the radial portion of the cord being now placed along the shaft, and having one of its ends attached to the collar, and the other to the shaft, so as to resist the motion of the collar produced by the pull of the cord. The force transmitted would then be measured by the position of this collar on the shaft. The method, however, shown in the diagram, of converting the tangential motion into a radial one, we consider preferable to the others just alluded to. H C is an arm, which, to combine considerable stiffness with lightness, is trussed in the plane of rotation as well as in a plane at right angles to this, as seen in the upper part of Fig. 3. This arm turns about C, a pivot on the rim of the loose pulley, and is moved by means of a link L L', attached at L by a pivot to the arm, and at L' by a pivot to the end of one spoke of the keyed boss, F F'. If now the loose pulley and the keyed boss receive an angular twist, the end, H, of the arm, to which a bright bead is attached, moves almost radially towards the shaft. The exact path of the bead H is shown in Fig. 4 for different positions of C. Supposing, for example, we regard the keyed boss at rest, and that C moves to the point marked 1, then L will also move to 1 in the other curve, and H will move to 1 in the path it describes.

To measure, then, the power transmitted by the engine to the machine, all that is necessary is to observe on a scale placed in a suitable position, the radius of the circle traced out by the bright bead H, and the number of rotations made per minute, both of which can, of course, be ascertained at any time without stopping the machinery.

An alternative arrangement which we employ with very stiff springs is to have a small pinion at L', which works into a short spur segment on the pulley. A very small relative angular motion of F F' and B B' produces in this case a great angular motion of the pinion, and therefore of a light arm which turns with the pinion, at the end of which there is a bright bead.

It will be observed that this form of transmission dynamometer is not only extremely convenient when the dynamo-electric machine is driven by a strap, but will be especially suitable when the machine is driven direct from the shaft of a fast speed engine, as, for example, one of Messrs. Brotherhood's three-cylinder engines. In such a case the shaft would really be in two portions, end to end, supported by suitable brackets; one keyed boss would be on one portion of the shaft, and an arrangement something like the loose pulley we have referred to would be on the other; but in this case it would, of course, be keyed to its portion of the shaft. Motion would be communicated from one portion of the shaft to the other through the spiral springs, and the extension optically observed in the manner we have described.

ARTICLES.

THE FUTURE OF ELECTRICITY.

THERE are few persons, acquainted with the recent progress of electricity, who are not prepared to agree with the opinion that the latter portion of the 19th century will be an era of a great and wonderful development of that form of energy which our immediate predecessors regarded as somewhat mysterious, and which we still regard as something rather inexplicable. An ingenious lecturer can make suggestions and prognostications as to the future applications of electricity, and we are ready to accept all that he says, for the simple reason that advance has lately been so rapid that we do not know how far we can go. The recent development of electricity in its applications to useful purposes has unquestionably been swift; but it should not be forgotten that many years of toil in the laboratory have been necessary before the knowledge we now possess was available to the masses. It is worthy of note that the labours, the fruits of which we are now beginning to reap, were carried on without that peculiar endowment of research for which there is in certain quarters so loud a demand at the present time. It is true that, by an abuse of terms, we may say that Faraday was endowed because he received a salary for holding an honourable situation to which certain duties were attached; but the endowment of research now demanded is a very different thing altogether, and is nothing less than the expenditure of public money in maintenance of people who call themselves scientific investigators, as distinguished from scientific professors who hold legitimate positions at our universities and colleges. In a paper read last week before the Society of Arts, by Prof. John Perry, the author said that it was for the good of the nation to provide scientific men with large laboratories, and acknowledged that he had prepared an hour's lecture, dealing with the subject of endowment of research; but, happily, he remembered that the members of the Society were acquainted with the truisms, and so he left it out, and proceeded with the subject proper, "the future development of electrical appliances." Passing over the first half of Prof. Perry's paper, which dealt with rather elementary points of the subject, we come to parts which contain statements of more or less importance to the future developments of electricity, points which require no "endowment of research" to explain. Thus Prof. Perry tells us that the true solution of the problem of electrical transmission of power was first given by Prof. Ayrton in his lecture before the British Association at Sheffield, in which he "showed" that the whole power of the falls of Niagara might be transmitted by a fine copper wire, if it could only be sufficiently well insulated. That Edison, Maxim, or Sawyer has not yet succeeded in transmitting the power of that gigantic waterfall to New York is, therefore, probably due to the difficulty of obtaining sufficiently good insulation. According to the laws enunciated by Profs. Perry and Ayrton, the power wasted is proportional to the square of the current flowing, whereas the power utilised is proportional to the current, and also to the electromotive force of the motor; hence, they argue that for the future development of the transmission and distribution of electric energy it will be necessary to use machines of great electromotive force, and they think that there is a future in this direction for the employment of such plate machines as that of Holtz. The electro-motive force of an electric machine may be increased, says Prof. Perry, by increased speed, by increased strength of magnetic fields, and by increasing the length of wire on the moving armature; and of these methods the first is the most important. He has discovered that if iron is used for the armature, its coercitive force prevents the magnetisation and demagnetisation being so complete at high speeds as at the ordinary speeds of the present day. The electric machines of the future will, he is convinced, be without iron in their movable parts; but, unfortunately, he does not say what is to take its place. The lifting-power produced in an electro-magnet is simply proportional to the heat produced in the wire on the magnet, and if it is our object to diminish this heat, we must discard all idea of working the magnets of electric machines by their own currents, and, according to Prof. Perry, use the smaller dynamo-machines with which we are familiar to feed the magnets of larger machines. His alternative is to fall back on magneto-electric machines. With such machines as he suggests—for we believe they are not yet constructed—he declares it would be possible to heat, light, and ventilate all the houses in New York, and to give to large and small workshops the power required to drive their machinery, by means of an ordinary telegraph-wire transmitting energy from as great a distance as the Falls of Niagara. There is one condition, that the method of insulation shall be exceptionally good, and that, we surmise, has not yet been discovered. However, this distribution of power from a single centre is, we are assured, a something to be looked forward to with perfect certainty in the future of electricity; and, assuredly, in this case, the larger will include the lesser. An electric railway has been a practical fact for some time; but if we may believe Professor Perry, the introduction of electric railways everywhere is merely a question of time. The electrician sees better insulation of the conductor and application of the principles utilised by Dr. Siemens to hundreds of miles of rails, instead of a thousand yards; he sees, in fact, that the larger the experiment the greater must be its success. There will not only be no vitiation of the air in underground lines, but the wear and tear of permanent way may become less than one quarter of what it is at present; for instead of heavy locomotives, each carriage will have its own driving and braking machinery, and the energy expended in stopping will not be wasted as now, but will be returned to the generator. Speaking of improvements which might be easily made, Prof. Perry referred to Mr. Schwendler's use of a dynamo-machine for furnishing the current needed for working telegraph circuits in India, and declared that it was absurd to fill houses with thousands of sloppy voltaic cells in order to work the telegraph lines. If we have not misunderstood Prof. Perry, he implies that our Post-Office authorities, in the experiments they made in this connection, blundered by using a machine far too small, and, of course, it failed. If that is so, the sooner the electricians at St. Martin's-le-Grand take a leaf from Mr. Schwendler's book the better.

Another point touched upon by Prof. Perry was the question of storing energy, and with the aid of a Leyden jar he had no difficulty in showing that it could be done in small quantity and for a short time. A thermopile had been working for nearly an hour, and had filled two test-tubes with oxygen and hydrogen respectively, which Prof. Perry said could be kept stored up for as long as was required. A windmill working a magneto-electric machine might be employed to produce a store of the two gases, which will yield up the energy again in the form of light and heat, or will reconvert it into electricity. Tidal power might also be utilised as well as that of the wind; but there are many little difficulties to be surmounted which in a popular lecture cannot be mentioned. Profs. Perry and Ayrton have recently made some experiments in the laboratory of University College which seem to them to promise great results. Zinc may be burnt in a Voltaic cell with almost perfect economy—that is, with the minimum of loss of the energy it is capable of producing; and it occurred to the experimenters that coal-gas also might be so burnt. The experiment, as shown at the Society of Arts, consisted in what may be termed the cold-burning of the gas, in which the energy is given out as electricity and without heat, therefore, without waste. A vessel containing some water is filled with gas, and a metal plate is so placed as to be partly in the water and partly in the coal-gas. This plate is connected to another metal plate outside, which is partly in water, partly in air. Electricity circulates in the wire connecting the plates, and may be transmitted to any distance. Professors Ayrton and Perry are constructing a generator of this kind which will be capable of working a sewing-machine, and the latter asserts that instead of wasting 99 per cent. of the energy of the coal—the usual waste in steam-engines—the coal-gas battery enables them to utilise the whole of the energy in a form in which it may be transmitted to any distance. We need scarcely say that the whole industrial world will await with impatience the advent of the first motor of this kind, and the gas companies will at any rate see how little they have to fear from electricians, for, if Professors Ayrton and Perry are not mistaken, there will be a gas-worked electric-motor in every house to which a gas supply is now laid on. Professor Perry also described some experiments he has been making, in conjunction with Professor Ayrton, with the phenomena of the telephone and photophone, and these investigations illustrate two important things—viz., the principle of recurrent effects in the use of the telephone has opened up a new path into unexplored nature; and the laboratory worker sees a hundred interesting phenomena which ought to be investigated at once, and which he cannot take up unless he gets more apparatus, more money, and more observing eyes and working hands. It is a pity that such a phrase should occur in the paper without a definite statement of its meaning. Professor Perry himself alluded to the fact that Birmingham men found Priestley with money to carry on his researches, and we venture to think there will be no lack of funds to carry on experiments tending to develop the applications of electricity; but if the principle of Government endowment of research is once conceded, where will it stop? There are hundreds of investigators who believe that their investigations, or rather the researches they would like to make, are of far more value than those carried on by Prof. Perry; and although we may know they are not, it would be difficult to silence the clamour for payment. Of the value of the investigations we have attempted to describe merely in outline there can be no question, and another important one is an idea of a water siren, the tones of which would be conveyed by the water itself to the

THE TIMES, SATURDAY, MARCH 17, 1883.

THE NEAR FUTURE OF ELECTRIC POWER.

Professor Ayrton, F.R.S., delivered on Thursday night, at the London Institution, the second of his two lectures on "Electric Lighting and Locomotion." It was as effectively illustrated by diagrams and working models of the most striking kind as the first, which was reported in *The Times* of the 24th ult., and there was a no less crowded and attentive audience.

The lecturer began with a recapitulation of the importance to be attended to in all large transmission of power by electricity to distant places. Great electrical pressure is of supreme importance, so that the serial working of lamps and motors is better than the parallel system. To insure safety, the going and return cables must be well insulated from one another as well as from the earth, and the current must be absolutely constant in its strength, not merely having the mean constancy attainable with many of the so-called constant current dynamo-electric machines. Many motors were shown in action, each coupled up directly to a drill or a fan or a circular saw, without intermediate gearing, and the lecturer laid great stress on the fact that one employment of electric power—viz., the driving of fans by electro-motors, appeared to him to be at the present moment of vital importance. For years past we had been breathing foul air in the Underground Railway. Much grumbling had resulted, but no ventilation, and at the present moment we were threatened with unsightly openings on the Embankment to let out the obnoxious gases. Now it was quite possible by means of comparatively small pipes to extract this foul air if fans were used; but inasmuch as fans were usually driven by steam engines and the smoke of steam engines was objectionable, it was necessary to drive these fans electrically. Electric fans of suitable size, placed at proper intervals, could receive as large an amount of power to drive them as might be desired through a single insulated going and return wire passing from motor to motor from a large dynamo machine outside the tunnel driven by a steam engine in some backyard, but giving perfect ventilation to the Underground Railway. It was difficult for the ordinary public or the mechanical engineer to understand what enormous power might be transmitted electrically through wires in the heart of a coal mine or in the middle of a tunnel. The lecturer pointed out that the motors on the table, which were capable of giving out half-a-horse power continuously for a long time, weighed less than 40lb., and were of very small size, so that, whether they were attached to a carriage to drive it or were to be used in some confined space, they were a very great advance on the steam engine. Comparative experiments were then made with a governed motor and a common motor having the same appearance, and it was shown that a change of load which diminished the speed of the ungoverned motor from 1,560 revolutions per minute to 509, reduced the speed in one of Ayrton and Perry's governed motors from 1,250 to 1,181 only.

The governing of motors so that they should run at a constant speed, whatever work they might be doing, was of considerable importance for the driving of lathes and other machinery, but for motors on electric tramcars, tricycles, &c., it was necessary to run at any desired speed forwards or backwards, and it was often particularly important that a motor should turn with very great force at the slower speeds. The lecturer then exhibited and described the use of the regulating handle, which he and his colleague had fitted to their motor for backward and forward motion at different speeds.

Having described many details in the electrical railways of the future, the lecturer entered on a consideration of the merits and defects of existing electric railways. The specimen at the Giants' Causeway he considered to be the latest and probably the highest development of the model so familiar to us years ago. He had ventured, however, to prophesy last year that when the old familiar idea of insulating the rail close to the ground for the conveyance of electricity to a distant train was attempted to be carried out in a damp climate, on a railway six miles long, the leakage would be so great as to prevent more than a very small fraction of the electric power reaching the distant train. The lecturer demonstrated this by an artificial rainfall, and said that of course this simple plan of working had to be discontinued at the Giants' Causeway and an elevated rail supported on wooden posts rubbed by brushes fastened to the train had been substituted. The objection to the elevated insulated rail was that on any but the simplest railways where no crossings occur it becomes impossible to use it.

He then described the system of Professor Perry and himself in the following words:—

"We electrically subdivide the rubbed rail into a number of sections all fairly, but by no means perfectly, insulated from the ground. We do not apply our electricity directly to this rubbed rail, but, instead, to a well-insulated conductor, which may be buried underground or may be insulated by resting like a telegraph line on insulators or posts, and we arrange that when ever a train enters on to any section it 'automatically' makes an electric connexion between that section of the rubbed rail and the well-insulated conductor which supplies the power and at the same time automatically cuts off the electric power from the section the train has just left, and in this way we confine the leakage of electricity to that section on which the train is at any particular time, and so reduce the leakage and waste of power on the longest electric railway to less than it is at present on the shortest line constructed on the Berlin plan. But not only does a train on entering any section automatically turn on the electric power to that section, and cut it off from the one just left, but it accomplishes something more; it blocks absolutely the section just left."

This was experimentally exemplified. So, too, whenever a train was approaching too near another in front, and was thus deprived of driving power, it was automatically braked. Whenever, then a train, even a runaway engine, entered on a blocked section, not only was all motive power withdrawn from it, but it was also automatically powerfully braked, quite independent of the action of signal-man, guard, or engine-driver. No fog nor colour blindness, nor different codes of signals on different lines, nor mistakes arising from the exhausted nervous condition of overworked signalmen could produce a collision. The common English system of blocking meant merely giving an order to stop. Their absolute automatic block acted as if the steam were automatically shut off and the brake put on whenever the train was running into danger; nay, it did more than this, it acted as if the fires were put out and all the coal taken away. The lecturer next entered on the question of the use of accumulators in electric lighting and locomotion, and showed that the transmission of electric power, whether for lighting or the driving of machinery, could safely be done by the use of accumulators. He said:—

"For the economic electric transport of power we must, as I have explained, produce a great difference of potentials by a dynamo at the place where the power is obtainable—in the suburbs, where, for example, is the steam engine or water wheel—and employ some mechanism which can be worked by the great difference of potentials at the place where the power is to be utilized—that is, in the town. There is no difficulty in arranging a dynamo wound with fine wire, or a set of dynamos in series with one another, to produce any difference of potentials required; but there is a far greater difficulty in using the great difference of potentials at the town end of the line. If lamps and motors of the present construction are used they would have to be put in series, but in that case if the current is stopped passing though one it will be stopped passing through all. This difficulty can to a great extent be avoided by using 'cut-outs,' as I described to you in my last lecture. At the same time nobody would be perfectly satisfied that his supply of electric power should depend on the good working of all the electric apparatus in the same street, much less that it should depend on the good working of all the electric apparatus in the same town. We are content that our supply of gas or water should depend on the good working of the gas or water works, but we could not tolerate the possibility of Betsy Jane, in Moorgate-street, through carelessness, being able to cut off our supply at the London Institution. What, then, are we to do? High difference of potential we must use, and we cannot work the lamps and motors in parallel unless they have a resistance of tens of thousands of ohms, in fact, are of a totally different description from the lamps and motors of the present day. The solution was first suggested by Sir William Thomson, in 1881, and I am happy to say will be very shortly carried out by Professor Perry and myself, under the auspices of the French Electrical Storage Company, in Paris. It is to use the small current and great difference of potentials to charge a very large number of accumulators, in series, in the town, and to discharge them in sets, each set supplying the energy for one street, or, possibly, for one district. Of course, the going and return wires between the dynamo and accumulators must be separately insulated, and put so far apart that there is no fear of a man or an animal accidentally touching both. If, in addition, it is feared that although this precaution is taken still somebody may touch a leading wire, this may be also entirely avoided by electrically disconnecting the various sets of accumulators from one another, and from the main charging wires coming from the dynamo before they are connected respectively to the local leads in the streets for being discharged."

After giving important practical confirmation as to the size and cost of copper wires for the safe conveyance of electric power to a distance, the lecturer showed how it was possible to charge the consumer of electricity, whether he used it for giving light or for driving machinery, so that he should just pay for the exact quantity of electric power he had used during the last three months. Ayrton and Perry's "Ergmeter" performed this function. The lecturer demonstrated that the different systems of lamps in use at the present time required different pressures in the mains, so that the money value of the ampere from Edison was twice as great as that of one ampere from Swan, and that even in any one system it was not possible to maintain the same pressure for all consumers. The pressure must vary according to the number of lights in use at the time, even if the pressure at some one particular house were kept constant. He showed that the working of machinery by electricity will probably be more important than lighting, since it will go on all day long, so that the meter wanted is one to measure electric energy and not the mere quantity of electricity.

After briefly describing the driving of boats and tram cars carrying accumulators, the lecturer went on to say that the latest development in the use of accumulators was the electric tricycle of himself and Professor Perry, the first tricycle ever propelled and lighted from accumulators. This tricycle was placed upstairs in the library, where the lecturer drove it round and round the room at considerable speed. The tricycle was one of a well-known firm, altered to suit the circumstances of the case. No work was done by the rider, but ten little black boxes carried on the base board contained the stored electric energy pretty much in the same way as a horse's body contained its breakfast of oats and hay, but with this difference—that in these accumulators it was the receptacle alone which had weight, so that neither in receiving its food in the morning nor in discharging the power during the day did the accumulator gain or lose in weight. The rider sat with the steering handle on the one side and on the other his electric supply tap. If he wished to go faster or uphill he increased his supply. The little motor, which was somewhat similar to the other motors exhibited during the lecture, was fastened under the rider's seat, driving the wheels by means of spur gearing. With this tricycle a measured mile had been run in 8½ minutes when carrying a man of average weight and enough accumulators to furnish power for a run of two hours.

Professor Ayrton, in conclusion, said—What stored electricity could do the accumulators before the audience had shown. What the future of electrical locomotion might be who could say? At present much household work was done by hand, simply because there were no easily worked machines for doing it. The old knife board had given way to the rotary knife-cleaner, but even that required a certain amount of grinding to give the knives a polish, so that for large establishments a knife-cleaner boy was still necessary. The blacking of boots, the blacking of grates, the cleaning of doorsteps, &c., were all done in a most laborious way by hand, judging from the anxious appearance of Sarah Anne after the process. Now there could be no doubt that very shortly electricity would be supplied, as gas was now, to houses for lighting purposes, and when this had been accomplished, the same wire that conveyed the electricity for lighting would be employed to convey the power to work electric motors to turn rotary knife-cleaners, to turn a wheel for the blacking of boots, and a small motor carrying a brush would simply be passed by the servant all over the grate for the purpose of giving it a good black polish. The black lead brush would then be taken off, and replaced by the blacking brush for the boots, and later on in the day a rotary flannel would officiate for the door steps.

Engineering, March 10, 82.

ELECTRIC POWER.

The latest novelty in the application of electric power is the driving of some piles to support a cofferdam across the River Lea at Hatfield Park, the seat of the Marquis of Salisbury. The power was transmitted by two dynamos connected by two conducting wires to a pile-driver on a barge in the river, and the dolly weighed from 4 cwt. to 5 cwt., and worked with ease and regularity. The first application of electricity to the propulsion of tramcars in England was made on Saturday, the 4th inst., at the works of the North Metropolitan Tramways Company, Leytonstone. The car employed was one which has already been tried in France. It is fitted with Faure accumulators under the seats, and connected to an electric motor beneath the car, acting by pinions on the wheels. The experiments were successful, and short runs were made along Union-road to the surprise of the spectators, who could see no visible driving. The accumulators weighed 30 cwt., and were charged to yield 25 horse power for an hour or 5 horse power for five hours. Thus the car could have run with its passengers for half a day allowing for loss of energy. The drawbacks are that the car and cells weigh so much—5 tons—and that the pinions make a disagreeable grinding noise, but this is of course only a mechanical defect. The experiments were undertaken by Mr. Radcliffe Ward on behalf of the Faure Accumulator Company, and the promoters hope to work the car at one-half the cost of horses, and also to drive cabs and omnibuses in a similar manner.

ELECTRIC CURRENTS.—Professor Sylvanus Thompson, of Bristol, delivered a lecture on February 22, at the Crystal Palace, on "Electric Currents: What are they?" This lecture is the first of a series which the directors of the Palace have organised in connection with the International Exhibition of Electricity. The lecturer began with an enumeration of the multifarious services now rendered to mankind by the electric current. Yet, though its applications were endless, it was remarkable how little was known of its intimate nature. To understand the true nature of electric currents, or even of electricity itself, necessitated a wide range of study, the more careful because of the great variety in the different properties and phenomena. Electricity might remain in the form of "charges" on the surface of bodies, or might flow through their substance in continuous "currents." Yet it was not a material fluid, and the term "electric fluid" was now only used by those who knew nothing about modern investigations in the science. Nevertheless a study of the various properties of electricity, the attractions and repulsions it set up, the sparks to which it gave rise, the chemical decompositions it effected, the magnetic actions it produced, all led toward a certain theory, only to be grasped when all these diverging lines were traced back to their logical origin. It was a matter of congratulation that so many eager and able scientific men were now devoting themselves to this youngest of the sciences, more especially as it was pre-eminently a British science. Almost every great discovery in electricity had been made by Englishmen. From the time of Dr. Gilbert, who founded the science in 1600, Englishmen had been foremost in electric discovery. Stephen Grey discovered that electricity could be made to flow in currents through wires; John Canton discovered the influence exerted by electricity at a distance; Benjamin Franklin, the inventor of the lightning rod, was a Briton, though resident then in Philadelphia; Humphry Davy, the discoverer of the electric light; Spencer, the inventor of electro-plating; Faraday, the greatest experimentalist in electric science that ever lived, to whose fundamental discoveries modern dynamo-electric machinery may be directly traced; Ronalds, Cooke, and Wheatstone, the fathers of the electric telegraph, and Swan, the inventor of the carbon-filament lamp, were all Englishmen, while Graham Bell, the perfector of the telephone, was Briton-born. Not that some great discoveries had not come from other lands. Cunæus, a Dutchman, discovered the Leyden jar; Volta, an Italian, discovered the voltaic cell; Oersted, a Dane, discovered the relation between magnets and electric currents; Reis, a German, invented the first rude telephone by which articulate speech was transmitted; and Planté, a Frenchman, invented the storage-battery or accumulator. After referring to the relation between the power of electric currents and the power that is spent in producing them, Professor Thomson spoke of the certainty that in the near future all heavy mechanical work would be done by electric currents in the place of steam, a theme which will claim further attention in a subsequent lecture. Developing the question of the production of electric currents in voltaic batteries, the lecturer referred to the discovery that such batteries were reversible, and that in this reversibility lay the newly-discovered power of storing or accumulating electric energy in cells which could be charged and discharged at pleasure. The magnetic, thermal, and physiological properties of the electric current were illustrated experimentally, the lecturer remarking with much emphasis that the mistake of confounding physiological with medical or remedial effects led to the gross impositions of the quacks and rogues who deal in so-called magnetic appliances, and disgrace alike the sciences of electricity and of medicine, while knowing nothing of either. The nature of electric currents was reverted to, and an outline was given of the theory of Clerk Maxwell that all electric phenomena were due to actions going on in the thin medium that fills the whole universe—the æther—vibrations of which are light and heat, the accumulations of which are electric charges, the streams in which are electric currents, and which, where it was made to spin round in vortices or whirlpools, gave rise to magnetic attractions. In conclusion, the lecturer commented on the immense importance of the revolution now beginning in the substitution of electric machinery for steam engines, and urged that if England desired to reap the benefit of this impending reorganisation of the methods of mechanical production, if she desired that her workmen should rise to the immense future before them, she must not lose an hour in providing them with an education in matters electrical, seeing that a knowledge of electric currents and their properties will be of far more practical importance than a knowledge of any other branch of science. If technical education did not come in any other way, it would be forced upon us by the practical fact that electricity is to be our servant in the place of steam and of coal.

74

Iron - April 1, 1881

THE FUTURE OF ELECTRICITY.—At the meeting of the Society of Arts, on Thursday evening last week, Professor John Perry read a paper, which was illustrated by many experiments, "On the Future Development of Electrical Appliances." He said electrical energy can be transmitted to a distance, and even to many thousands of miles, but can it be transformed at the distant place into mechanical or any other required form of energy nearly equal in amount to what was supplied? Unfortunately, hitherto the practical answer made by existing machines is "No." But, fortunately, Joule's experiments and other facts tell us that in electric machines of the future and in their connecting wires, there will be little heating, and therefore little loss. We shall, at no distant date, have great central stations, possibly situated at the bottom of coal-pits, where enormous steam-engines will drive enormous electric machines. We shall have wires laid along every street, tapped into every house, as gas-pipes are at present; we shall have the quantity of electricity used in each house registered as gas is at present, it will be passed through electric machines to drive machinery, to produce ventilation, to replace stoves and fires, to work apple-parers and mangles, and barbers' brushes, among other things, as well as to give everybody so electric light. It had been supposed that to transmit the power of Niagara Falls to New York a copper cable of enormous thickness would be needed. Professor Ayrton showed that the whole power might be transmitted by a fine copper wire, if it could only be sufficiently well insulated. He also showed that the one thing preventing our receiving the whole of our power was the mechanical friction which occurs in the machines. He showed, in fact, how to get rid of electrical friction. Professor Ayrton and himself had come to the conclusion that very large continuous current machines, with separate exciters, or perhaps even magneto-electric machines, driven very fast by steam-engines, will have an important place in the future transmission of energy by electrical methods. With such machines it would be possible to heat, light, and ventilate all the houses in New York, and to give to large and small workshops the power required to drive their machinery by means of an ordinary telegraph wire (but with some exceptionally good method of insulation), transmitting energy from as great a distance as the Falls of Niagara. The experiments of Dr. Siemens showed that there could be no doubt that the introduction of electric railways everywhere was merely a question of capital and the sacrifice of much existing plant. This kind of proof was very much needed by capitalists. But the electrician saw much further; he saw better insulation for the conductor, and application of the above principles to hundreds of miles of rail instead of a thousand yards; he saw, in fact, that the larger the experiment the greater must be its success. He looked forward to the absence of a vitiated atmosphere in our underground railways. He saw that the weight of rails (for there would be no heavy locomotive in the future, each carriage would have its own driving and breaking machinery) and the cost of bridges and wear and tear of permanent way might become less than one-quarter of what they are at present; he saw, in fact, all the advantages that would arise, when, instead of making a heavy steam-engine travel backwards and forwards with carriages, the carriages alone travel, and the steam-engine is not near the railway at all. After a number of interesting experiments bearing on the subject of the storage of energy, the lecturer concluded by exhibiting models to illustrate his belief that it will become possible by electricity to enable a man in London to see an occurrence going on in a distant town.

Engineering March 1883

ELECTRIC TRANSMISSION OF POWER TO GREAT DISTANCES.

The recent experiments of M. Deprez in transporting power by electricity from the workshops of the Chemin de Fer du Nord have attracted much attention. An ordinary telegraph wire of 4 millimetres diameter and 160 ohms resistance, running between Paris and Bourget and back, a distance of 17,000 metres, was the conductor employed. The two machines were also connected by another short wire; the conditions of working being the same as if they were placed in relation to each other at a distance of 8500 metres, and connected by a going and returning wire. The generator had a double bobbin wound with wire 1 millimetre in diameter, and was of peculiar form in the armature. The receiver was a large Gramme machine of the military type modified to suit the occasion. The resistances of the two machines were 56 and 83 ohms respectively. All the electric and other measurements were carefully made during the trials which took place last month; the former being made by Dr. J. Hopkinson, F.R.S. The mean result of six trials on February 11th showed that 2.03 chevaux (each cheval being equivalent to 75 kilogrammetres per second, or 0.9863 horse-power) were transmitted of the whole 6.21 chevaux registered by the dynamometer at the transmitting station. This corresponds to a return of 0.327 H. P. per horse-power absorbed. A detailed examination of the transmitting system shows that the resistances of the generator, the heat developed therein, the loss at the brushes and in sparking, absorb 30 per cent. of the energy. Another 30 per cent. was lost in the passage of the telegraph line; or, in other words, 122 kilogrammetres of energy were dissipated in the conductor. The resistances of the receiver with its wires and brushes also absorbed some 30 per cent. of the electric work. Thus each of the three working parts of the installation had an efficiency of 0.70. Roughly speaking the energy actually transmitted to a distance of 8.5 kilometres (about 5.3 miles) by an ordinary iron telegraph wire of 4 millimetres in diameter, represents one-third of the original quantity.

75

THE DEPREZ SYSTEM OF ELECTRICAL TRANSMISSION.

SINCE 1873, when M. Fontaine made his historical experiment at the Vienna Exhibition, illustrating the transmission of force by electricity, a wonderful advance has been made in the utilisation of the principle demonstrated in that experiment; and in Europe, as well as in the United States, electricity as a motor may be said to have almost—not quite—reached the development necessary for a widespread though not economical application. We have already described in some detail the motor of M. Trouvé, that was exhibited in no very practical shape at Paris; and we may now interest ourselves with a more important arrangement—the electric motors of M. Marcel Deprez. Although Mr. Edison, amongst others, appears practically to have solved the problem of subdivided transmission of power, up to the present employers of the electric current either for the production of light, for power, for electrotyping, &c., are all obliged (except for incandescence lighting) to be the producers also, and to procure a more or less important plant for the generation of the currents they require. They are, in fact, in the position of a gas consumer who, instead of receiving his supply from the mains, has to manufacture it for himself. Central works for the production of electricity, as they exist in London, at Charing Cross for lighting the Thames Embankment, or in Paris in the cellars of the Opera for lighting the Place and the Avenue, are only special establishments for the one or two clients who light and extinguish all their lamps at the same time, and work their generators under fixed conditions. The same thing applies to the transmission of power. The valuable principle of reversibility on which such transmission is based, has up to the present been applied only within narrow limits by manufacturers who find it economical to have an installation for producing the power and transmit it to the points where it is to be utilised by the aid of two connected machines. So far, however, nothing at all comparable to the distribution of gas has been done, no system by which, from a central establishment, a *réseau* of lines is laid in different directions to supply light, to drive machines, or to use for heating purposes. In such an arrangement each consumer would be independent of his neighbour; he would open and close his meter when he pleased; light, regulate, or put out his lamps; apply the current to his motors, or heat his apartments—none of these operations would involve any inconvenience to the other consumers in the same *réseau*. This is the principle to be perfected for the popular and domestic application of electricity—the principle Mr. Edison is putting into practice, which M. Deprez has utilised, and which, as far as power is concerned, is already the business of a large company in Philadelphia, who are introducing the Griscom motor.

We have now to do with the system of M. Deprez, and we will postpone for a future article the simple explanation of the method which he has followed in working out his system, and will limit ourselves to-day to explaining the principle in a general manner, and to describing the installations at the recent Palais de l'Industrie. Let us suppose that M, Fig. 1, is a dynamo-electric machine producing a

FIG. 1.

current, and that A A^1, B B^1 are two copper conductors attached to the terminals serving as the points of departure to the exterior circuit. If we connect the ends of the two wires, the current will circulate by reason of the difference of potential at the points A B, or rather by the electromotive force of the machine. If instead of this we connect certain points a a^1 a^{11} of the first conductor with corresponding points b b^1 b^{11} on the second conductor, the lines a b, a b^1, &c., will receive partial currents, the intensities of which depend on the difference of potential at the points a b a b^1 a b^{11}. If then by any means the connexions can be so made as to render their difference of potential constant, whatever may be the number or extent of the branch lines, the passage of the current will be equal in each of them, and it will be possible at will to suppress or establish any number of the branch currents without interfering with the circulation in the others. Each branch would thus be entirely independent, and the mechanism it drives would work without variations due to other mechanism being thrown in or out of operation. This is the problem proposed by M. Deprez, and which he has solved with great success. Further on we will describe by what series of deductions he arrived at his system of automatic potential regulation; for the present we will confine ourselves to the way in which it was carried out at the Exhibition of Electricity. M. Deprez's patents are the property of a syndicate, and the apparatus which secured for their inventors diploma of honour, were exhibited by M. Guichard, who it may be remembered was one of the earliest to interest himself in the Jablochkoff system of electric lighting. It was at his works indeed that the first experiments of M. Deprez were conducted that have since been developed on a large scale, and were shown so extensively at the Palais de l'Industrie.

The current transmitted and divided between the various apparatus by which it was employed, was produced at the Palais de l'Industrie by an Otto and Langen gas engine driving a Gramme machine, modified as we shall indicate on a future occasion, and excited by a small Siemens machine. These were placed in the middle of the group of motors installed by the syndicate, and behind the exhibit of the French Gas Engine Company; the position is marked M on the annexed plan, Fig. 2. We may mention here the velocities of the machine — 800 for the

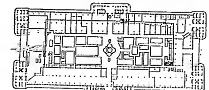

FIG. 2.

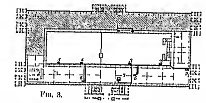

FIG. 3.

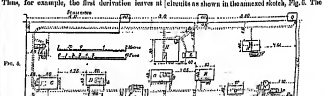
Gramme machine, and 2000 for the Siemens. The two main conductors from which the various branches were led off have a special peculiarity. If they had been arranged as shown in the first figure, it will be seen that the successive derivations would be made at constantly increasing distances from the machine. More favourable conditions are obtained by bringing back each conductor to its point of departure, and in leading off each deriva-

FIG. 4.

tion at an equal distance from the point of departure and the point of arrival of the two conductors. Thus, for example, the first derivation leaves at the point α, Fig. 4, at 50 metres from the first binding screw of the conductor A, and is connected at β at 50 metres from the end of the conductor B. If the total length of the conductors be 1000 metres, which was the case at the Exhibition, it will be seen that all the points of derivation correspond to an equal length of main conductor, that is 1000 metres. On the two accompanying plans, Figs. 2 and 3, of the ground floor and the galleries of the Palais de l'Industrie, respectively are shown the direction of the main circuit. After leaving the machine the conductors were raised and followed the ceiling of the main machine gallery. The first branch taken off fed a small Marcel Deprez motor (which will be described further on) which drove a light shearing machine for metals, with about one-twentieth of a horse power. This machine, which was exhibited by M. Bunon, is marked *l* on the plan, and was placed behind the Hermano Lachapelle engine. The branch wire was of copper .9 mm. (.036 in.) in diameter, and 72 ft. long for the whole circuit. The main conductors then continued along the ceiling of the gallery past the buffet, and descended at one of the columns supporting the main staircase, to the principal exhibit of Deprez motors. The annexed sketch shows the arrangement of this exhibit, which comprises no fewer than fifteen different apparatus working together, or individually, with absolute independence. It was easy to test this during the Exhibition by starting all the machines together, and then stopping them excepting one, an experiment which invariably showed that the speed of this latter was not modified, and that it continued to work without being in any way affected. The plan shows the general arrangement of the main circuit, and the approximate positions of the derivations. The apparatus worked on this circuit were as follows (see Fig. 5).

A wood-cutting machine A is driven by a small Deprez motor; *b* is the table on which the wood is placed; *a* represents the motor; C is a sewing machine, D a plaiting machine, E a sewing machine, F a small copper chain-making machine that was exhibited by M. Hunon; G is a gauffering and plaiting machine. All these were driven by separate Deprez motors. On the table H was placed a Deprez galvanometer and a Gülcher lamp J. These two, as well of the Lane Fox incandescence lamps K, and the Siemens machine L, were on successive sub-circuits as shown in the annexed sketch, Fig. 6. The other installations were as follows: M is a gauffering machine shown by M. Tuquet; N is a plaiting machine, and P a wood-cutting machine; these also were worked by separate Deprez motors. The sew-

FIG. 6.



LITERATURE.

Roorkee Hydraulic Experiments. By Captain Allan Cunningham, R.E. Printed and published at the Thomason College Press. In Three Volumes. Roorkee, 1881.

This large and important work, giving full detail of one of the most extensive series of hydraulic experiments made in recent times, consists of three volumes; the first of text, consisting of nearly 400 pages, mostly in rather small type; the second of about 200 pages of tables, mostly in small type, the latter part of which consists of abstracts from the preceding 150 pages; the third of fifty-two plates illustrating the subject.

The experiments, conducted on a large scale under the auspices of the Indian Government, had for their main object, to obtain further and more precise information on hydraulics that would be of use to engineers and others connected with the large canals of India; the specific primary objects being:

I. The discovery of a good method of discharge measurement.

II. Testing the applicability of known mean-velocity formulæ.

III. The discovery of a good approximation to mean velocity.

The whole of this to be applicable to large bodies of water in distinction to the results of the French hydraulic engineers obtained from experiment on small branch channels, such as the Bief de Bourgogne. The experiments on the flow of water were made on the Ganges Canal and its branches between December, 1874, and March, 1879, in which period there were some intermissions, at the comparatively low expenditure of 5400*l*. The main results and deductions gained were the following:

1. Loaded tube rods give a rapid and sufficiently close approximation to mean velocity past a vertical. They are so convenient that they should supersede all other instruments for the purpose, in depths not exceeding 15 ft.

2. With good arrangements, discharge measurements obtained under similar conditions by the system advocated, may be expected not to differ more than three per cent.

3. None of the known mean-velocity formulæ appear to be of really general applicability. Kutter's appears to be the most general. The approximation likely to be given by it falls far short of that given by direct discharge measurement.

4. Central mean-velocity measurement appears to be the best means of rapid approximation to mean sectional velocity; but the reduction must at present be effected by a coefficient to be found by previous special experiment at each site.

Among the minor or secondary results, the following are a few of the more interesting:

5. The motion of water in large open channels is essentially unsteady. Even in long straight fairly uniform reaches, the velocity at any point is extremely variable from instant to instant, and the stream lines interlace freely in all directions.

6. The water surface is not sensibly convex across the channel.

7. The average velocity surface is, as a rule, convex throughout.

8. The maximum velocity past any vertical is, as a rule, below the surface; the depression increases from the centre towards the banks in a rectangular channel. The depression is not much affected, if at all, by wind.

9. Loaded rods nearly grazing the bed move slower than the mean velocity past them; so that to measure mean velocity past a vertical, their immersed length should be decidedly less than the full depth.

10. The mean velocity at a given site depends more on the surface gradient (which is determined by the state of control above and below the site), than on the mere depth of water at the site.

11. A discharge table for a given site must hence be necessarily one of at least double entry, showing the discharge as depending on both surface gradient and gauge reading.

A general review of the whole results obtained is thus verbally expressed by the author himself.

"The general result of this work may perhaps be considered in some way disappointing, in that there are no brilliant results, no simple laws of fluid motion discovered, not even a new formula proposed for mean velocity; the complexity of fluid motion becoming indeed the more apparent, the more the conditions of experiment are varied. Nevertheless, the author submits that on the whole the practical objects proposed have been attained, and that taking this together with the great scientific interest of the other results, the great outlay on this work has been usefully incurred."

This review certainly errs on the side of modesty; the expenditure on such a large series of experiments over so long a time and at such a place appears small; the discovery of new simple laws could not for a moment be expected by any one very conversant with hydraulics; the pursuit of a chimera in the form of an entirely new formula, as that of Gordon, could be nothing more than a disappointment to those pursuing it; the main practical results have been obtained, and these are exactly such as might have been legitimately expected by many hydraulic engineers. Their importance, however, should not be underrated. Apart from a perhaps excessive confidence in tube-rod measurement of mean vertical velocity, due rather to relative performances than absolute precision, the conclusions drawn from the experiments, affecting vital matters in hydraulics on a large scale, are of high interest to scientific men, to all professional men whose duty it is to be well informed on such subjects, and to the general public that are inevitably affected directly or indirectly by all scientific results.

Although a very few, with unusual opportunities of observation joined to unsparing labour, might have foretold the results in broad terms; although the columns of ENGINEERING have for several years past advocated such principles as are now proved to be substantially correct on a large scale—the mass of professional and scientific men have long remained undecided on the most important points. The sweeping condemnation of all calculated mean velocity formulæ, with the exception of that of Herr Kutter, is now fully borne out by experiment; and as to the correctness of the Kutter coefficients, the following is the verbatim statement:

"Kutter's coefficient is one of pretty general applicability; when the surface slope measurement is a good average, that coefficient will give results, whose error will probably seldom exceed 7½ per cent. in large canals."

There can now be little further hesitation on these points except among those that will not read, or those who, seeing, will not perceive; no longer will the old hydraulic tables be used, and the world is relieved from a sea of error. The value of such knowledge cannot be over-estimated. The other valuable result gained is the knowledge that the depression of the locus of maximum velocity past any vertical is not much affected, if at all, by the wind. This will open the way for the future of experiment and observation, and place velocity observation on a firm basis, a matter of very high importance.

While thus giving a cursory notice of the book treating of these experiments and their results, we postpone the detailed examination of the experiments themselves to future numbers of this paper, as their importance carries them beyond the limits usually assigned to literary notices, and into the wider subject of hydraulics generally. The pains-taking labour involved in the experiments, the difficulties to be surmounted, the ability shown, and the excessive elaboration of detail in these volumes, combine to place Captain Allan Cunningham in the first rank of hydraulic engineers of the present age, and to rescue Englishmen from the charge of being behind Continental scientific men in such matters.

Fehland's Ingenieur Kalender for 1882. Berlin: Julius Springer.

This engineer's pocket almanack, which we briefly noticed last year, has again come to hand, revised, altered, improved and brought up to date. It is truly astonishing where these numerous engineers' pocket-books find a market in Germany, still their number increases every year, and the old-established books would soon find themselves behind if their contents were not carefully revised for each new edition. In this respect they form a striking contrast to our own technical pocket-books.

In Mr. Fehland's calendar for 1882, several chapters, particularly those on iron and steel-making, have been completely rewritten. The Thomas-Gilchrist process is treated upon, and the Bessemer and Siemens-Martin processes have been brought up to date; it almost appears that the author has taken advantage of the meeting of the Iron and Steel Institute meeting at Dusseldorf last year to embody the latest information in his handy and useful pocket almanack. Other chapters on mechanical construction have been corrected and improved, a railway map of Central Europe will also be welcomed by many, and a variety of information on postal, telegraph, and other matters of general interest, readily explains the fact that most German engineers always carry one or the other of these engineers' pocket calendars about with them.

THE ELECTRICAL TRANSMISSION OF POWER.

In our last number, we described the method devised by M. Marcel Deprez for the electrical transmission of power to a distance. His remarkable success in dealing with this important problem is due, in great measure, to his thorough mastery of the theory of electrical work. We shall endeavour briefly to give his views of this subject as we find them in a paper recently communicated by him to *La Lumière Electrique*.

When a battery is used to effect chemical decomposition, work is done both in the electrolytic cells and in the battery itself, the latter being reckoned positive work, and the former negative. The absolute amount of work done, however, does not vary from point to point, but remains constant throughout the circuit, as was shown by Faraday, and embodied by him in his celebrated laws of electrolysis. If we couple together N cells, say, of Grove's gas battery, and place n voltameters in the same circuit, the latter will set up an electromotive force opposite in direction to that of the battery. If E be the electromotive force of one cell, N E will be the electromotive force due to the battery, and n E that due to the voltameter. Their ratio is $\frac{n E}{N E}$ or $\frac{n}{N}$. Since the chemical action is the same in every part of the circuit, it follows that the quantity of gas which disappears in each battery cell will be precisely equal to that evolved in each voltameter. If V be the volume consumed in unit time, the battery will absorb N V, and the voltameter will give out *n* V volumes. The ratio is $\frac{n V}{N V}$ or $\frac{n}{N}$, a numerical expression for the ratio of the negative to the positive work, and at the same time for the ratio of the electromotive forces.

When $\frac{n}{N}=1$, the positive and negative electromotive forces neutralise each other, and consequently no work can be done. We also see that according as N increases the number of units of work produced diminishes. A certain portion of the current is also converted into heat, owing to the resistance of the circuit; and it is in this new form that we must look for the balance of the energy which is developed by the battery and does not appear as useful work.

The distance which separates the two parts of the circuit must not be neglected. Its effect may be calculated and even eliminated. M. Deprez has found that the chemical work done in the battery, and the chemical work produced by the current at any point of the circuit, are independent of the intervening distance when the respective positive

LITERATURE.

Die Maschinenelemente, ihre Berechnung und Construction. By PROFESSOR C. BACH. Stuttgart: J. G. Cotta. This work, intended as a text-book for technical educational establishments as well as a book for reference in the drawing office, is accompanied by an atlas containing forty-two plates, independently of numerous woodcuts in the text. Professor Bach devotes the early part of his work to chapters on elasticity and strength of materials, and treats this subject on the basis of the series of experiments conducted by Professors Wöhlert and Bauschinger, with a view to establish the amount of fatigue produced on materials when subjected to a series of strains continued for long periods and varying in intensity. It will be remembered that by these experiments, extending over a number of years, it was proved that even very minute strains, if only repeated for a sufficiently long period, would ultimately result in a molecular change of the material. The practical conclusion to be drawn is, not to base calculations of strength of material, in whichever way strained, on the ultimate breaking load, but rather on the elastic limit, which was ascertained for various materials, and various modes of straining by these experiments. A large number of Professor Wöhlert's experiments are actually given, and corresponding conclusions drawn therefrom, most of which, however, have for years been objects of every-day practice. That sharp corners are detrimental to test bars or plates, particularly in steel, has led to carefully planing the edges of steel plates for boiler work and for other purposes.

Rolled plates tested by Professor Bauschinger showed, after having been once strained, an increased resistance in the longitudinal direction of fibre, but a decrease when strained transversely. In straining materials three principal modes of operation were employed: a bar loaded with a dead weight, a bar bent in one direction only for an unlimited number of times, a bar bent in all directions for an unlimited number of times, and for these three distinct groups Professor Wöhlert's experiments give as result the proportionate numbers 3 : 2 : 1.

Tensional strain is taken as the unit; for shearing only 0.8 of this is admitted, while for torsional strain 0.4 is the result finally arrived at for all materials except cast iron.

The author further points out the necessity of carefully considering the conditions under which the same material may be strained, and quotes that for instance it would be quite wrong to allow a driving belt to be strained as heavily as a belt or rope used for lifting a load as in a hoist.

In the second part of the work which deals with elements of machinery, the author carefully avoids proportioning any parts according to empirical formulæ, which are misleading to the student, and carry no correct idea of the strains involved, but in all cases calculates them according to the amount of strain they have to bear. To this part of the work, the illustrations in the atlas principally refer; the early chapters, treating on wedges, keys, screws, rivets, &c., we may pass over without any remarks. In his choice of calculations and sketches for a steam boiler intended for 75 lb. working pressure, the author is not happy in assuming single-rivetted joints, in giving two pages of calculations on the exact shape of the plates, forming a conical ring of the shell, and then calculating at length the number of rivets required. He shows, moreover, in the sketch, the gusset stays fixed close behind the end plate seam, and the longitudinal seams close together, so that the drawn out plate corners may fill better; these are misleading points to the beginner. Gearing and cog-wheels are next treated, followed by pulleys and general notes on driving both belt and rope, and are profusely illustrated. Amongst the bearings we notice several novelties, and special attention is paid to self-adjustable bearings and bearings admitting of fixed adjustment in various directions; a four-parted crankshaft bearing on Plate 17 is of very neat design. Pistons, stuffing-boxes, cranks, eccentrics, and other engine details follow, mostly of sound design and of modern construction, only occasionally we meet with illustrations of types which it would be best to forget rather than reproduce in a new work; among the latter might be classed some of the expansion joints shown and described; nor is the author very happy in his design of pump valves on Plate 39, which would probably give some trouble at high speeds.

The work as it is—the second part can only be called descriptive of the atlas of plates—is a very good and useful book to assist the young designer, and has the great advantage over most of its rivals that mostly new and good types are illustrated in it; its value would however have been materially increased had each chapter contained some general hints on designing the particular part under consideration, instead of simply giving a list in words and the picture of forms generally used. It is not in the want of form that the young engineer mostly fails, but in the judicious selection of the most suitable under certain conditions, and some general notes would here be of great value, although of course experience is the best teacher.

The Book of Scales. By A. W. HOLOHAN. London: Longmans, Green, and Co.

This is a somewhat elaborately got-up book on the construction and use of scales, particularly intended for students at military academies, and when first opened it rather conveys the idea that military students are not credited with too large an amount of common sense, for, in constructing ordinary scales for drawing purposes, such as for instance one inch to a chain or a mile, or a proportional scale of one in 260, we do not recollect having noticed such difficulties as the author evidently assumes to exist amongst students. However, the subject of scales is exhaustively and carefully treated and excellently illustrated, and if the author errs, it is certainly on the right side, the explanation being rather too complete than otherwise. In fact, a student might open the book of scales at any page, and without referring back, be able by the information there given regarding the particular scale he requires be enabled to lay it down on his drawing paper. The first plate contains a comparative table of English linear measures from one mile down to one inch, with all intermediate divisions, from which the equivalents may be read off at a glance; this is the handiest table of its kind we have yet seen. When speaking of foreign, principally Continental, measures and English equivalents, the author gives all the old measures now mostly abolished in favour of the metric system; this may be very useful to have, but a note to the effect that almost all Continental nations now use the metric system, and have done so for about ten years, should have been added. Good and plain descriptions are given of a number of drawing instruments and their application, examples being in all cases quoted; these include the sector, the protractor, the clinometer and oometer, and the book finishes up with some exercises on scales. To all not experienced in drawing, and also for handy reference to English and foreign measures, the book will prove useful, and to the student the excellent style in which the scales given, are drawn and divided, it will be a useful guide, while the latter part treating on the protractor and its various combinations, may be considered a text-book on a subject not frequently treated elsewhere.

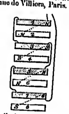
JABLOCHKOFF'S ALTERNATING CURRENT GENERATOR.

IN a previous number (see page 391 *ante*) we referred to the general conditions which led M. Paul Jablochkoff to elaborate a type of electric generator which should avoid as far as possible the small causes of deterioration which are inherent to the Gramme ring, and which may result in more or less costly repairs. It is this object which is explained in the French patent of the 25th September, 1878, by M. Jablochkoff, for "Improvements in the construction of magneto and dynamo-electric machines," and the specification begins thus: "The improvements we have introduced in the construction of magneto and dynamo-electric machines have for their object the improvement in the working of such machines, the increase of their duty, or the reduction in the motive power they absorb, and to facilitate their maintenance and repairs." The generator to which this patent refers, after having been studied theoretically by M. Jablochkoff, was brought to a practical form only a long time after, when the inventor had returned to Paris from a protracted stay in Russia. It is shown in Figs. 1 to 4 on the next page, which represent the general arrangement of the first type constructed for feeding sixteen lamps. It will be seen from these engravings that it consists of eight electro-magnets of a helicoidal form. To avoid the serious difficulties that would be met in the construction of the spiral electros, if they had been formed in a single piece, they were made in a series of stars of plate iron from three to four millimetres thick, with eight branches, and pierced with a hole at the centre; these were mounted on an axis, one against the other, and to each a slight angular advance over the preceding one was given; by this means the desired spiral surface was obtained. The eight branches are connected by locking bolts passing through the stars, and the steps formed by the angular advance are reduced to a continuous surface by filing, or other mechanical means; the core formed in this manner is externally solid and compact, and not likely to be injuriously affected by the action of centrifugal force. We shall moreover see, further on, that the speed at which the Jablochkoff machine is driven is sensibly less than that of other generators. On the inclined surfaces of the core, coils are wound in which the current of the exciting machine circulates; this is ordinarily a direct-current Gramme of the ordinary workshop type; the coils are kept in place by the form of the arms of the core. We shall see presently that these coils are wound in such a way as to give contrary magnetisation to the successive poles. The fixed coils receiving the induced current are formed in a somewhat similar manner to the inductors, being made of a series of iron plates one millimetre thick, placed together so as to form a flat core. The annexed sketch

shows the form of these plates, which are held together by four clips. The wire is wound around these cores perpendicular to their length, that is to say in the direction of the motion of the armature. This is evidently a good arrangement as regards the safety of the machine. If any wire from the electro-magnets should become detached from the core, the movement of the armature would tend rather to protect than destroy it. In the core of the electro-magnets the plates are separated from each other by thin pieces of paper, which prevent the creation of currents injurious to the proper working of the machine, and reduce the tendency to heating. The magnets, the form and arrangement of which are shown in Figs. 1 and 2, are fixed by two copper armatures held at their ends by two rings attached to the frame. Their dimensions, and that of the wire covering them, are so calculated that each of them corresponds to a normal Jablochkoff candle of four millimetres diameter, so that a generator with sixteen magnets is also a sixteen-light machine. If in the course of working, one of these magnets is disabled, it is very easy to remove it and replace it in a few minutes by a spare one, an advantage peculiar to this machine. On account of the special characteristic of having each magnet to correspond to one lamp, it is possible to make the exchange when the generator is at work, by simply cutting out the lamp corresponding to the magnet being shifted, and without extinguishing the other lights.

The following are some general particulars of the 16-light machine of the first type that was experimented with at the works of the Jablochkoff Company, 61, Avenue de Villiers, Paris. The generator,



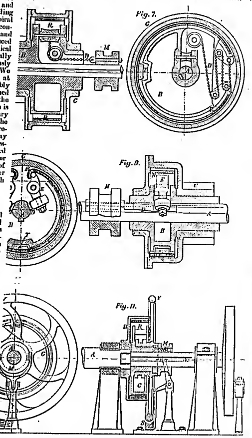
arranged as described, was furnished with a current from a Gramme exciting machine revolving at 750 revolutions per minute, and furnishing a current of

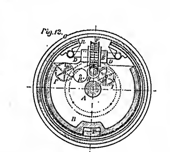
...bjects which indicate ... working. It utilises ...luced by a flat plate ...d dimensions, and its ...tion of a pulley in which ... produce an elastic brake. ...artially the pressure of ...a complete or partial ..., the brake mechanism ...spring, carrying on its ...intended to produce the ... the inner face of the ...oduced. This spring is ... the pulley and keyed on ... the spring is free to ...or band around its edge

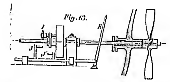
arising from shocks is avoided, and the motion is always very easy and regular. Motion to the spring is communicated by several different means; we may first notice that used for the Jablochkoff generator. This is represented by Figs. 6 and 7, which are, respectively, a longitudinal section and a face view. The driving shaft is shown at A; on it is keyed the sleeve B; C is the pulley mounted loose on the sleeve; R the spring which almost entirely covers the inner face of the pulley. It carries a stud T which engages in a corresponding recess in the sleeve, and determines the adhesion of the spring and the sleeve, when they are connected. The retraction of the spring is effected by means of the outer sleeve M, to which a chain is connected, running over a series of rollers. When

ward, and, consequently, draw the ends of the spring towards each other. Figs. 10 and 11 show an arrangement worked with a pedal. In this case it is required to make fast or loose two shafts, A A', one of which forms an extension of the other. The driving shaft is A, and it carries the pulley B; the sleeve C is keyed on to the shaft A'. The flywheel V runs loose on the sleeve C, and moves with A' by the clutch M; the chain of the spring is fixed to the flywheel by one of its ends. It will be seen that by pressing on the pedal, the sleeve M slides from the flywheel, of which the movement is then rendered independent of that of the shaft A'; the shoe s stops it, and the spring is operated through the chain.

Lastly, Fig. 12 shows a further modification.







The two shafts occupy the same relation as in the preceding arrangement; the sleeve B is keyed on the shaft A, and the box C on the shaft A'. The ends of the spring are connected to two rods screwed in opposite directions which enter the nut E; the toothed wheel F gears into an endless screw. It will be seen that the movement of the latter regulates at will the relative position of the ends of the spring. The worm carries a toothed wheel H which gears into the wheels H H', the axis of the former is a palette wheel I. The wheel H' gears into the wheel H'' carrying on its axis a second wheel I'; the sleeve B carries with it in its movement the wheels I and I'. By means of the lever K a rod is worked having two fingers J J' which can be placed in the plane of rotation by the wheels I I' turning them, and consequently actuating the pulley mechanism. To prevent the spring from being forced on itself or against the box C, if the lever is not withdrawn in time the wheels I I' are free to shift on their axis. The movement can be regulated in such a manner, that beyond a certain point the fingers J J' are free of the palettes. Fig. 13 represents this system applied to driving a screw shaft.

...ce of the pulley, and consequently ...connexion of the latter with ...ley is then fixed. This pres... ...ta maximum, and consequently, ... is produced, the pulley would ...covering of the spring, up to ...no friction would have absorbed ...o. By this means the danger

the sleeve is moved it acts upon this chain in the manner shown in Fig. 7. We have already indicated the special mechanism by which the sleeve M is moved in the Jablochkoff machine.

Before concluding this article we may indicate three different modifications made in the Mégy pulley. In each case the action of the spring on the face of the pulley controls the apparatus, the means of actuating this spring constituting the difference. Figs. 8 and 9 show an arrangement in which wedges are made use of. Here the chain is replaced by two levers E, the upper ends of which act on the ends of the spring. The lower ends of the lever carry two rollers, and the lateral movement of the sleeve forces, between the shaft and the rollers, two wedges which are pushed for-

THE ELECTRICAL TRANSMISSION OF POWER.

(Continued from page 592.)

THE machines of Pixii and Pacinotti were the prototypes of the two great classes of electric generators now in use. In the one the armature revolves between the poles of strong steel magnets; in the other large masses of soft iron are converted by the action of the current developed in the armature itself, into powerful electro-magnets, which in turn produce an intense magnetic field.

Iron – July 18, 1884.

ELECTRICAL TRANSMISSION FROM NIAGARA FALLS.*

By Mr. Benjamin Rhodes.

Dynamic electricity is used substantially only for the electric light, but this has become a great industry. It is the object of this paper to show what has been done and what may be done toward the utilisation of Niagara for electrical purposes. The power of Niagara can be estimated very approximately. The average flow of the river, according to the many careful measurements, is 275,000 cubic feet a second. The fall through the rapids immediately above the falls is 65 feet. The height of the falls is 165 feet, making a total of 230 feet; thus we have for the whole power 7,000,000 horse-power. To utilise this amount of power by water-wheels, generate electrical currents, and transmit to various cities within 500 miles would necessitate a plant representing at least $5,000,000,000. Such figures as these give some idea of the enormous amount of power here in reserve. A small proportion of the power of Niagara is already utilised, and a much larger amount can be developed at moderate cost. On the Canada side, the entire use is represented by a small overshot wheel under 6 feet head, which has for many years propelled a solid piston single-acting pump, furnishing a meagre supply of water to the adjoining village. On the American side, along the rapids on Goat Island and the mainland, there are five separate raceways using from 4 to 16 feet head, and developing in all from 800 to 1,000 horse-power, most of which is now in actual use. If the project for the appropriation of lands at Niagara for a state reservation is carried out, all these races will come within the fixed bounds of the park, and will, of course, be odious in the eyes of the commissioners and be swept away.

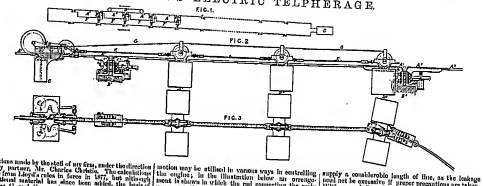
The greatest power now in use at Niagara, however, lies outside the proposed State Park. It is the Hydraulic Canal, and was constructed about 1855. It is cut through the solid rock across the peninsula on which the village of Niagara Falls is built, taking the water from the extreme head of the rapids and discharging below the falls, giving opportunity to use the entire head of 230 feet. The canal is nearly one mile long, and was planned 100 feet wide and 10 feet deep. It has been excavated but 70 feet, and half the distance it is but 35 feet wide. It is at present partially filled with débris, being at certain points no more than 5 feet in depth. At the lower end is a basin nearly at right angles with the canal, which may be extended as needed along the river frontage belonging to the Hydraulic Power Company. The canal lay idle for a quarter of a century, and it remained for an enterprising citizen of Buffalo, Mr. J. F. Schoellkopf, possessed of a large capital and zeal, to open up this great power. At the time of his purchase—in 1878—there was only one water-wheel on the canal. There is now a large and increasing number of buildings for manufacturing purposes distributed along the high bank of the river, using an aggregate of nearly or quite 5,000 horse-power. The wheels in these buildings are set under heads of from 50 to 100 feet, and discharge the tail water over the side of the precipice, the various streams falling over 100 feet to the river below. Some of these wheels are of large size when the head is considered, several being capable of giving from 1,100 to 1,500 horse-power each. The last two years have seen great improvements in the making and setting of wheels, and the working of all the mills is now regular and continuous. Further developments of power at Niagara may be made at little expense. The Hydraulic Canal can be deepened and widened and wheels may be set under greater heads, the total amount thus made available here being equal to the necessities of many years. Large powers may also be developed at Goat Island and Prospect Park in case the State Park plan is not effected, in either place 10,000, 25,000, or even 50,000 horse-power being easily available. It may safely be said that the use of Niagara has just begun. Low water is unknown, troubles from ice are slight, hours of use are not limited to eight or ten, but twenty-four hours in the day, and 365 days in the year, and unlimited power is ready, making this the most reliable, as it is the grandest, water-power in the world.

The application of the water-power of the Niagara to electrical purposes has been limited, being hitherto confined to the local use of the electric light, but this use has been such as to give much valuable experience. A Brush dynamo has been in use in Prospect Park for the illumination of the falls and grounds, since July 4, 1879. This machine is run under peculiarly favourable conditions, having always the same number of lamps in circuit, with power supplied by a water-wheel of proper capacity, and the plant operated only two hours of each day. The working has always been smooth. A Weston dynamo, with a Serrin lamp and reflector, was for some time used to light the beautiful rapids in the rear of the Cataract House; some difficulty was found with this plant, not, however, due to the power. Several isolated Edison installations have been made in various mills, the dynamos in each case being run by the water-wheel that furnishes power for the mill. While the power is continuous the light is excellent, the only difficulty with such a plant being that, in case of shutting down for repairs, auxiliary power must be supplied for the dynamos or other light used. A local Brush company was formed in the fall of 1881, and has since been lighting the streets and dwellings of the village of Niagara Falls with from forty to sixty lamps. The company has met with not only the usual difficulties of such organisations, due to inexperience and the sudden introduction into general use of new machinery and unfamiliar principles, but in addition other troubles due to the interruption to the power from various causes, so that a steam plant has been maintained by the side of the water-wheel. As heretofore noted, the improvement in power has been marked, and it is probable that the steam plant will be used hereafter only in such extraordinary emergency as might be classed with the bursting of a steam boiler or the destruction of a building by fire. Experience has shown the immense difference in cost between the use of steam and water-power. Electric street lights are furnished profitably at a price much lower than at any other place, and if the number were greater, the price could be still further reduced. The future application of Niagara's power to electrical purposes is an interesting subject. The local use will keep pace with the growth of the town, but will of course be comparatively small. In order profitably to transmit currents of electricity to a distance, several conditions must be observed: The cost of transmission must be less than the difference between the cost of steam and water-power; the distant point must be one where the currents of electricity can be used, and where water-power cannot be obtained.

There is no point so likely to fulfil these conditions as the city of Buffalo, and the project must be proved practicable there before being attempted in larger and more distant cities. The estimates following are based upon the Brush system, not on account of merit in this beyond other systems, but because it happens to be there in most general use. There are in Buffalo 400 arc lights, requiring the use of steam plant of about the same number of horse-power. The number of lights is increasing as in other cities, and it may be assumed that there will be 1,000 lights in use within two years. The length of circuit required between Niagara Falls and Buffalo is about fifty miles. Experience has shown that from forty to sixty lights can be run on one circuit with an electro-motive force of from 2,000 to 3,000 volts, but a greater number requires a current of so great intensity as to be in some danger of burning the insulation on the dynamos as at present constructed. There is no doubt the dynamos will hereafter be improved in this respect so as to permit 100 arc lights to be in the circuit. As the resistance of the circuit and consequent loss of power vary directly as the length and inversely as the area of the wire used, there will be found for every case a size of wire such that the sum of its cost and the capitalised loss of power will be reduced to a minimum. The size of the wire will be less for water-power than for steam. The cost of erection complete of a number of circuits of proper length would be about $4,000 per circuit. The resistance would be 70 ohms—equal to 16 lamps; or, assuming the very general practice of coupling, in series, a 40-light and 16-light Brush dynamo, the loss would be about 28 per cent. The total power at Niagara Falls may be assumed at $10 per horse-power per annum, delivered on the shaft. The cost of transmission will be interest, repair, and depreciation, which will be all covered by 10 per cent. on the investment. The items of cost of dynamos, carbons, lamps, and care of lamps are common to the use of steam and water, and need not be considered. The most enthusiastic advocate of steam-power will hardly claim that it can be produced for from ten to twelve hours a day at less than $50 a year, and as used for electric lights with small engines the cost is actually nearer $75. The saving then may safely be assumed at $40 a year, or, on a plant for 1,000 arc lights, the sum of $40,000 yearly. Enough has been said to show that the power of Niagara can be transmitted to a distance of twenty-five miles with a great saving over steam, and that, with improvements in storage batteries and electro-motors, this distance can be increased with economy to from 100 to 150 miles. With further improvement in dynamos and insulating material, to permit the use of currents of higher intensity, the economical distance may be still further increased.

81

JENKIN'S ELECTRIC TELPHERAGE.



culations made by the staff of my firm, under the direction of my partner, Mr. Charles Christie. The calculations were from Lloyd's rules in force in 1877, but although additional material has since been added, the basis of Tables G and G_2 remains the same, and therefore I reproduce the diagram (see Fig. 7). The additional material required by the rules at present in force would carry the curve of material higher up, as shown. The curves, which have been derived from actual calculation in each instance, show clearly enough that while the strains vary as the square of the length, the material to meet them varies more nearly as the first powers. It must be noted that in this particular calculation the midship section is assumed to be the same with each different length, wherefore the strains vary as the squares, not as the cubes, of the lengths.

As regards differences in model, seeing that strains depend so directly upon proportionate dimensions and upon displacement, it will probably be generally conceded that a wide door for error is left open when these are attempted to be averaged. The co-efficient of fineness of displacement, reckoned from the top of the keel to the load-line, has been in vessels recently built as high as .81 or .82, and I suppose in some vessels of special type it will be found to be below .50. In Fig. 7, I give the strains relatively with models of .50 and .78 of the parallelopiped taken to the bottom of an ordinary keel.

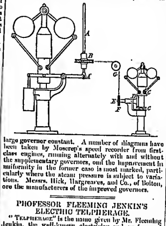
The classification societies, forming their rules tentatively, have preferred, not perhaps unnaturally, to make out tables and prescribe rules, both based largely on practice, rather than to enunciate principles or simply to prescribe a limit, as the Board of Trade do in the case of bridges. It is not therefore easy, or even possible, to say how far any of them recognise the depth of the girder as an element of strength. The calculations shown in Fig. 7 refer to the practice of one society only. Similarly as regards an added constant for corrosion, it is not stated how much is allowed.

It is probable that changes will ere long be made in the rules of one or all the classification societies. Many shipbuilders are far from satisfied, and it is in every way undesirable that we, the builders, who are the designers and constructors, should not be content with the regulations of those who in so many respects assist us and aid us, and to whose funds we are the principal contributors.

KNOWLES' AUTOMATIC SUPPLEMENTARY GOVERNOR.

It is well known that the action of a centrifugal governor produces only an approximate uniformity of speed in a steam engine. For every position of the throttle valve, or of the trip mechanism of the automatic expansion gear, there is at a given pressure a corresponding speed of the engine, not usually differing greatly from the determined speed, but still sufficiently to be of importance in many industries, particularly in cotton spinning, where the machinery is normally run at its highest possible velocity for good working, and is especially sensitive to sudden fluctuations. Many attempts have been made to produce governors that should not be subject to this disadvantage, but hitherto with very slight commercial success. Lately, however, Mr. Wm. Knowles, of Bolton, has devised an exceedingly simple and effective method of overcoming the difficulty. Instead of seeking to produce a theoretically perfect governor that should have no margin of error, he has adopted the existing type, and has corrected its variations by the aid of a supplementary apparatus, whose action is intended to be limited to the small difference of speed, corresponding to the difference between the highest and lowest working positions of the governor balls. This supplementary apparatus consists of a small centrifugal governor, having upon its spindle two friction discs, situated so far apart that there is room for a friction bowl to be placed between them. When the engine runs at the normal speed both the friction discs are clear of the edges of the bowl, but the slightest alteration in speed, either upwards or downwards, brings one plate in gear with the disc, and thereby rotates it. This motion may be utilised in various ways in controlling the engine; in the illustration below an arrangement is shown in which the rod connecting the main governor to the automatic expansion gear, is lengthened or shortened by means of a right and left-handed nut driven from the friction disc of the supplementary governor. A A' are the two parts of the rod; B the nut, carrying a grooved pulley; C C the friction plates, D the friction disc, and E a pulley that transmits motion to the nut B.

It will thus be seen that the main work of governing the engine devolves, as in the past, upon the large governor, which can be set to any required degree of sensitiveness and rapidity of action, while the hitherto uncorrected variations, due to the different positions of the governor balls, are compensated by the small governor, which reduces or increases the length of the rod A in such way as to maintain the plane of the



large governor constant. A number of diagrams have been taken by Moscrop's speed recorder from first-class engines, running alternately with and without the supplementary governors, and the improvement in uniformity in the former case is most marked, particularly where the steam pressure is subject to variations. Messrs. Hick, Hargreaves, and Co., of Bolton, are the manufacturers of the improved governors.

PROFESSOR FLEEMING JENKIN'S ELECTRIC TELPHERAGE.

"Telpherage" is the name given by Mr. Fleeming Jenkin, the well-known electrician and professor of civil engineering in the University of Edinburgh, to a system which he has devised for transporting vehicles, containing goods and passengers, to a distance by the electric current independently of any control exercised from the vehicles themselves.

The system has been patented, and it is to be hoped that a practical trial of it will soon be made. Professor Jenkin's idea is to employ strained metal cables which will serve both to sustain the load and convey the electric current. The frames or trucks supporting the load run along the cable on wheels, and the cars or loads are suspended below them from the axles of the wheels.

In the simplest arrangement of the line there is a break of continuity at each post supporting it; and the sections of cable are themselves insulated from each other, and the earth. They are, however, capable of being connected by movable coupling pieces, actuated by the train, so that all the sections receive the exciting current and form part of the general circuit.

The current is supplied to the line by a stationary dynamo-electric machine driven by a steam engine or other motor; and since the line is elevated from the ground on insulating standards, the same dynamo will supply a considerable length of line, as the leakage need not be excessive if proper precautions are taken. With ground lines of electric railway, like that of Siemens or Edison, the leakage is very marked, and Mr. Edison has adopted the plan of dividing the whole line into short sections of a few miles, with stations and feeding dynamos at each. Dr. Werner Siemens favours the use of an insulated conductor supported beside the line, and giving current to the motor on the train by means of a running connexion pulled by the train. Professor Ayrton and Perry have, as is well-known, sought to overcome the leakage difficulty by making the line in very short sections, each of which is put in circuit with the dynamo in turn as the train progresses, by an automatic action of the train itself. In this way there is only one section electrified at a time, namely, that over which the train is running, and the leakage on the whole line is consequently very small.

The loads or cars on the telpherage line are connected together in trains, and the length of a train is nearly the length of a section of the cable or conductor. On passing either of the movable coupling pieces between two sections, the train throws it out of action, disconnecting the two sections at that point; but the circuit between these sections is maintained through the wheels of the train itself and a conductor on the train. In circuit with this conductor is a dynamo-electric motor, which is actuated by the current, and propels the train by driving the wheels. The power provided is more than sufficient to keep up a maximum speed, and the train is provided with a governor which, when the speed is sufficient, closes a shunt and allows the current to pass without traversing the coils of the electro-motor. The governor acts directly to check the train if the speed becomes excessive, by short-circuiting the electro-motor, or otherwise bringing electric brakes into operation.

To further insure that one train shall not overtake another, Professor Jenkin provides an automatic telegraphic communication along the line, and the trains in passing close and open the telegraphic circuits. This automatic telegraph actuates circuit closers between the different sections of the main cable or conductor, so as to maintain connexion between the sections for a certain distance behind the train quite independently, it may be, of the movable coupling pieces. It is obvious that a following train entering upon a part of the line in which the sections are thus connected will have its speed checked, as the application of the power upon the train depends upon there being a break in the electrical coupling between the two sections on which the train is for the moment supported.

It will be seen from the above description that the control of the trains is completely automatic and independent of the guards or engine drivers. Fig. 1 will serve to explain the system more clearly. Here A^1 A_2 A_3 A_4 are separate sections of the insulated cable, and B B B are bridge pieces which establish metallic connexion throughout the series of insulated sections, so that wherever there is no train on the line the sections are coupled together and form part of the circuit. At one end of the line C, there is a stationary dynamo supplying a constant current to the circuit, despite the variations of resistance caused by more or less trains upon the line. A train on the line between sections A_3 and A^4 is indicated at D; and the length of this train is such that it always spans at least one of the junctions between two sections. The train, as it enters on a new section, removes the bridge or coupling piece B, which connects this section with that in rear, and thus compels the current, in order to maintain its circuit, to flow through a connecting wire or conductor G_1 (Fig. 2), on the train in which one or more electric motors are connected. These serve to turn the wheels of the cars by proper gearing, and propel the train.

traders, instead of passing through a middle man, and being swept away to the Presidency towns, to be subsequently remitted to England.

THE ELECTRICAL TRANSMISSION OF POWER.

(Concluded from page 619, vol. xxxii.)

In the transmission of energy by electricity we have to consider not only the generator, but also the instruments and various machines that may be placed in circuit. There may, at a given moment, be many of these, and at another only a few; so that the total energy required to meet these different cases is a very variable quantity. The whole energy, we know, is represented by the product of the electromotive force and the current (=E I). Hence we have two ways of varying this product, viz., by varying both factors simultaneously or each of them separately. The latter, however, is alone eligible on account of its simplicity. If we wish to keep I constant, we must arrange the receiving instruments in series; then as every change in the number of machines in circuit produces a corresponding change in the current, it will be further necessary to be able to vary the potential of the generator accordingly, *i.e.*, we must be provided with some kind of a potential regulator.

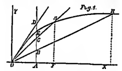
If we prefer to keep E constant, we must connect the receiving machines as we would the cells of a battery "for quantity." A moment's reflection will show that even this system will not always work without a regulator; for let the current from the generator be sent through a circuit of resistance R, then $I_1 = \frac{E}{R}$. If we now insert a machine of resistance R, the whole resistance will be halved so that $I_2 = \frac{2E}{R}$, and there would be sufficient surplus current to work the second machine.

But this assumes the internal resistance (r) of the generator to be *nil*, which is plainly inadmissible. We should have $I_1 = \frac{E}{r+R}$ and $I_2 = \frac{E}{r+\frac{R}{2}}$, whence it does not follow that $I_2 = 2 I_1$, nor can we say that the second machine will work effectively.

In both cases a regulator is required which will vary the electromotive force E of the generator, so that the difference of potential at the terminals may be permanently kept at a certain value e, notwithstanding the introduction of machines into the circuit or their withdrawal from it. This implies three conditions: 1, that each apparatus shall receive its share of the total energy and work independently of the others; 2, that the regulator act instantly and automatically; 3, that the regulator control the generator in such a way that the latter will produce just the quantity of electricity required for the service of the machines then in circuit. It is obvious that the arrangement in series is the less favourable to the realisation of these three conditions, for the various instruments, when thus connected, are much more dependent upon one another than when arranged "for quantity." M. Marcel Deprez in the investigation published in *La Lumière Electrique*, and which are following, has examined this somewhat complex question, and applied the graphic method to its investigation. He has succeeded in this way in explaining several curious and imperfectly understood phenomena observed in dynamo-machines, and also in showing how the above conditions may be carried out in practice. We shall proceed to give the principal theorems, applying them to any continuous current machine, say a Gramme.

We commence by making two distinct circuits of the armature and electro-magnets. Around the latter we send a current of known strength. Then starting the armature we measure the electromotive force corresponding to this speed V_1. We next vary the current, keeping V_1 constant, when we shall find for each value of I a definite electromotive force E. We draw two lines at right-angles for our axes and measure I along X and E along Y. We shall obtain in this way a series of points which, when connected together, will give a curve that quite characterises the machine driven at the speed V_1. This curve, called the "characteristic," depends for its form and properties upon the construction of the machine, its dimensions, and the relative disposition of its parts. Such a curve is shown in Fig. 1 and the following diagrams.

If now we restore the former connexions and drive the armature at the speed V_1, the current I developed in the armature circulates round the inductors thus producing the magnetic field. Let O F (Fig. 1) be marked off equal to I, then O G H



being the "characteristic" of the machine, F G will be the corresponding electromotive force. Ohm's law gives $I = \frac{E}{R}$ whence $R = \frac{E}{I}$, and applying this to Fig. 1, we find that $\frac{E}{I}$ is the tangent of the angle F O G. The resistance of the circuit is thus represented by the tangent of an angle.

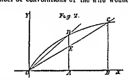
If we chose to diminish the resistance, *i.e.*, the angle F O G, the line O G would approach the axis of X, and, from the concavity of the curve, we see that the electromotive force would increase rapidly at first, then slowly, until ultimately it becomes constant. The curve then reduces to a straight line parallel to the X.

This phenomenon is explained by the changes which take place in the magnetic conduction of the inductors. The magnetisation increases rapidly at first with the current, and almost imperceptibly as the point of saturation is approached.

On the other hand, if instead of diminishing we increased the resistance, the line O G would rise towards the axis of Y; and for a certain position, viz. O D, would become tangent to the curve at the origin O. The electromotive force would then entirely vanish, and the machine cease to work. This is the phenomenon of the demagnetisation, and Fig. 1 shows that there is a definite resistance, viz., the tangent of D O A, for which the inductors are completely demagnetised.

When we have determined the "characteristic" for a velocity V_1, we can readily draw that corresponding to any other velocity V_2. It will be obvious that we have simply to multiply the ordinates of the first curve by the ratio $\frac{V_2}{V_1}$.

If we keep the velocity constant, and change the number of convolutions of the wire wound round



the armature from t_1 to t_2, we shall obtain the new curve by multiplying the ordinates of the first by the ratio $\frac{t_2}{t_1}$, providing, however, the volume of the wire has not been materially changed.

This graphic method also furnishes a convenient way of determining the difference of potential e between two points of a circuit of resistance R+r, separated by a known resistance r.

In Fig. 2, take the angle D O X such that tan. D O X equals R + r and C O X such that tan. C O X=R. Then from the figure, we have:

$$\text{D A}=\text{O A tan. D O A}=\text{I}(\text{R}+r)$$
$$\text{E A}=\text{O A tan. C O A}=\text{I R}.$$

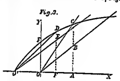
Therefore, by substraction,

$$\text{D A}-\text{E A}=\text{D E}=\text{I}(\text{R}+r)-\text{I R}=\text{I}\,r.$$

And by Ohm's law, I r equals e the difference of potential at the two ends of the circuit r through which the current I is passing.

As a particular case, let tan. C O X represent the internal resistance of the machine, and let the total resistance be variable. Then when the resistance equals tan. D O A, D E will be the difference of potential e at the terminals of the machine. Let D O coincide with C O, then e is *nil*; moving away from this position of coincidence towards the axis of Y, e will gradually increase until it reaches a certain maximum, after which it will rapidly decrease until it again vanishes when D O becomes tangent to the curve.

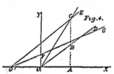
It may be important to consider the consequences of having an initial magnetic field. This may be obtained by winding the inductors with two separate circuits. If a current from a battery or a second machine be sent through one of the circuits, the magnets will be "made" and will give rise to the primary magnetic field. Let O' F C, Fig. 3, be



the "characteristic," obtained as before, *i.e.*, when an independent current is sent round the inductors. Let O'O represent this current, then O F will be the electromotive force, and F will be the starting point of the new "characteristic" due to the combined action of the independent current and that induced in the armature, so that the only change occasioned by the initial "field" is the transformation of the origin of co-ordinates from O' to O.

If we examine a carefully drawn "characteristic," we shall notice that it does not materially differ from a straight line until we approach the point of saturation of the electro-magnets; and we know, moreover, that by increasing the masses of these, the point of saturation may be further removed, and the rectilinear portion of the curve lengthened out.

Let O' G, Fig. 4, be the rectilinear characteristic of a machine. On superadding a constant magnetic field, produced by a current O' O, the characteristic will, as we have seen, be represented by the portion of O' G beyond the new axis of Y, viz., F G. If D O X be the angle whose tangent represents the internal resistance of the machine, F G and O D will, in general, intersect; and, as the portion of the ordinate intercepted by these two lines represents the difference of potential e at the terminal of the machine, it follows that this difference is a very variable quantity. But we have been led to conclude that this e must be kept constant in order to distribute effectively the electrical energy of the generator to a number of machines arranged "for quantity," and Fig. 4 shows how this may be



accomplished. For, by increasing the speed of the armature, the line O' G will be displaced towards the axis of Y, and, for a certain speed of the armature, it will take the direction O' C parallel to O D. The difference of potential e will then be always equal to C B whatever the resistance C O X of the circuit may be.

We see, therefore, that we must begin by raising the speed of the machine to a certain value V. Then if E_0 denote the electromotive force of the constant external current used in "making" the field magnets, and E the whole electromotive force $\frac{E - E_0}{I}$ will, since E and E_0 are represented by ordinates, denote the tangent of the angle which the rectilinear characteristic makes with X. For the required parallelism, this expression should be equal to the tangent of the angle denoting the internal resistance r. If it be not, we must find the velocity V' such that

$$\frac{V'}{V} \cdot \frac{E-E_0}{I}=r,$$

whence we get

$$V'=\frac{r\,V\,I}{E-E_0}.$$

The strength of the independent current and con-

84

The last equation may then be written

$$V = \frac{r V I}{E - E_n},$$

which is identical with that already found for the quantity arrangement.

From this it follows that the speed of the armature necessary to tilt up the "characteristic" to the required parallelism is exactly the same whether the receiving machines be arranged for quantity or in series. In the former case, it will be remembered that the armature and electro-magnet circuits are separate, and that an independent current of determined strength is required to make the "field." The whole current induced in the armature is then available for useful purposes. In the second case, the field magnets are excited by a current derived from the armature, and we are thus left with only the balance for external work. The main difference between the two cases lies in the connexion or separation of the two circuits, and as this can be effected automatically, it follows that by fitting up a generator with a commutator we can use it for the distribution of electrical energy to any number of machines all of which are arranged either for quantity or in series.

We may notice, in conclusion, that in the preceding ingenious methods and contrivances, we have compelled the electric current itself to so adjust the system as to enable us to dispense altogether with a mechanical potential-regulator.

The correctness of the principles involved in the graphic method, has been confirmed only by laboratory experiments as yet. It is proposed, however, to apply them very shortly on a large scale. The results will be of much theoretical and practical interest.

THE ELECTRIC LIGHT AT THE PORT OF HAVRE.

In a large number of tidal ports the entrance or departure of ships can be effected only twice in the twenty-four hours at the time of high water. Varying with the season the high tides occur, either both when the sun is above the horizon, or one during the day and the other at night, or both during the night. From this it results that during the period of long nights, that is to say, especially the period for bad weather, ships are often obliged to wait for several days, either for a bright night or for the next day tide, either for going in or out of port, which causes not only loss of time, and delay in commercial operations, but a serious loss of money. It is a less evil when the ship is at anchor in port, than when it is outside waiting to come in, liable at any time to damage from storm which might have been evaded if the ship could have entered harbour at once. Of course many ports do not present difficulties that render it dangerous or impossible for vessels to enter or leave on the night tides. In all cases, however, it is true that with ships, especially large steamers, the handling of which requires great caution, the responsibility of captains is very great, and a mistake easily made in the darkness may result disastrously. For a long while the chambers of commerce and the directors of ports and harbours have been occupied with the efficient lighting of entrances, a necessary complement to lighthouses and port and signal lights. This is almost impracticable with gas, which has too small a range to illuminate properly even the entrance and locks. Latterly, in many instances this has been partially done by electricity.

The port of Havre was the first to which a complete system of electric illumination has been applied, and a glance at the general plan shows how usefully these means of lighting could be employed. We reproduce in Fig. 1, a general plan of that part of Havre which includes the port and harbour, and it is necessary to devote a little space to describing the arrangements, in order to show clearly the services rendered by the electric installation, services that will doubtless be extended there before long. The port of Havre consists, as will be seen, of an entrance channel giving access to the outer port. This channel is 90 yards wide, and is formed of two masonry jetties. The north jetty, 1482 ft. long from the shore to the end, has a projection of 360 ft. on the ground enclosing the principal part. The projecting part exposed to the sea on two sides is constructed entirely in masonry. Beyond that on the one side two breakwaters are formed, consisting of a chamber on an inclined plane terminating on the side of the channel by a sill on which is raised a grid that allows the waves to enter the chamber, and there break their force. The southern jetty, which was 787 ft. long, is to-day partly destroyed, there only remaining a length of about 160 ft. The outer port has an area of 27¾ acres, with a development of 5157 ft. of quays, of which only 2276 ft. are made use of for business purposes, representing 886,000 sq. ft. of quay area, on which are distributed seventeen cranes for loading and unloading merchandise. This port is quite dry at low water; it gives access to eight floating basins, entered by locks, and there are four dry docks. The eight basins are respectively known as le Roi, la Barre, la Floride, l'Eure, la Citadelle, le Commerce, le Vauban, and le Dock. These have a total area of 131 acres, and a development of 29,356 ft. of quayage, of which 26,333 ft. are utilised, giving an area of nearly 13,000,000 square feet available for storing goods, and other purposes. The oldest of the basins is that called le Roi, which prior to 1820—an epoch at which the population of Havre was only 20,000—constituted almost the entire port. At this time the Commerce and the Barre basins were opened for navigation; the Vauban dates from 1841. But the commercial development of the port of Havre dates really from 1844, when the old

of protective coatings of gutta-percha, rubber cloth, and three thicknesses of paraffined hemp wound alternately in opposite directions so as to cover the joints completely; then follows a covering of galvanised iron wire, and finally a thickness of hemp. The necessity for this great precaution in protecting the conductors will be understood, when it is remembered that the cable has to pass through five locks, so that for the greater part of its length it is under water. It was necessary that the insulation should be as perfect as possible, as the same current has to feed simultaneously six candles, and consequently to possess too high a tension to be preserved except with the greatest care. Crossing the locks was one of the most delicate details of the work. All the conductors were held together by wire, and at low water they were laid from barges, and to avoid being dragged, they were held down by pig iron placed over them at frequent intervals; the two ends of the cable were raised and fixed against the sides of the lock. At the point where there was any danger of contact with the sides of vessels, they were recessed in a groove made in the masonry, and covered with cement.

At the passage of the Nôtre Dame lock the conductors are shielded behind the large cast-iron mains which convey the water and gas, and which protect them from injury. But it has happened that despite this very substantial security, this point is the only one where an interruption to the circuit has taken place. It was caused by the rupture of the water main, which damaged the cable. This injury was repaired by splicing, the only instance of the kind in the whole circuit, it having been avoided elsewhere by an arrangement to be described directly. The operation of splicing was a very delicate one, since the joints were likely to form weak spots in the system, and in this particular instance they were almost always under water. The conductors at the ends of the cable to be joined were stripped, the central wire in each was suppressed, and the strands were twisted in the manner shown in Figs. 11 to 13. Before joining the

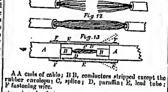

Fig. 11. Fig. 12. Fig. 13.

A A ends of cable; B B, conductors stripped except the rubber envelope; C, splice; D, paraffin; E, lead tube; F fastening wire.

strands, a lead sleeve was passed over the end of one of the conductors, having about the same diameter and about triple the length of the splice. This sleeve, fastened to the cable by a wire serving, was widened at the other so as to make a bell-mouth, and melted paraffin was poured in, filling the space between the splice, the stripped cable, and the lead tube. When the paraffin was solidified, the lead tube was hammered down and fastened to the other part of the cable by wire. The operation is illustrated by Fig. 13. On all other parts of the circuit, as we have said, splicing was avoided, the length of the cables having been carefully computed beforehand and made accordingly. The circuits were so arranged that the junctions of the different cables on the same line were made at the same points, where pits were made so as to give

Fig. 14.

facilities for examination and repair. These pits were made as follows. The cables, where they are laid in the ground, have a depth of about 18 in. below the level. At the points where the ends had to be united, a pottery cylinder was placed into which the two ends were raised, having been previously stripped; the strands were then connected by a copper locking-piece. After this has been done, plaster-of-paris is poured into the cylinder, embedding the turned-up ends of the cable. When this has solidified, melted paraffin is poured in, in such a way as to enclose the junction; finally cement is added on top and made good to the top of the cylinder, which is covered over with a cast-iron plate. The object of this arrangement was not only to reduce expense but also to simplify examination, in case of loss of current, by limiting it to an exactly defined spot. The total number of these junctions in the whole system is 24. Where the cables pass under the breakwaters of the jetties as mentioned above, they are secured by iron cramps, and by staples fastened to the timber framings.

The effect produced by the 33 candles distributed as explained, and as shown on the plan, Fig. 1, cannot be easily imagined. As we have said, the installation has succeeded beyond all expectation, and has been unanimously approved by the Chamber of Commerce as well as by the engineers and captains of vessels, and the pilots of the port. The utility will be soon increased by the addition of some new lights, and by raising the existing ones. It is also proposed to paint white the adjacent houses and the walls of the locks, in such a way as to transform them into reflectors, and facilitate still further the passage of ships. During the last six months the installation has been in full work and has been of great service, especially to the Transatlantic vessels, some of which are 380 ft. long, and to the Hamburg line, which is used largely for the transport of emigrants.

The whole of the work was carried out by M. G. Descomps, engineer of the Compagnie Générale d'Electricité, from the plans of M. Henry Parent, engineer-in-chief to the company, and under the control of M. Bellot, ingenieur en chef des Ponts et Chaussées, and of MM. Widmer and Delerme. We are glad to be able to give the names of all those who have taken part in this interesting installation, which is one of the most important yet undertaken in connexion with the electric light, not on account of the number of lamps, but because of the numerous difficulties that the requirements of the case and the location presented, and which have all been so fortunately overcome.

ENGINES OF S.S. "MEXICAN."

We give this week a two-page engraving containing two views of the compound engines of the s.s. *Mexican*, a vessel which is being built for the Union Steamship Company by Mr. James Laing, of Sunderland. The engines for the *Mexican* are being made by Mr. George Clark, of the Southwick Engine Works, Sunderland, and they were amongst those which were seen in progress by the members of the Institution of Mechanical Engineers during their visit to these works in August last. We shall in an early number publish further illustrations of these engines, and for the present, therefore, we postpone any detailed description.

COLD-AIR MACHINES.

TO THE EDITOR OF ENGINEERING.

SIR,—The letter signed by Mr. J. W. de Golwey in your issue of the 30th has already appeared in the pages of your contemporary *The Engineer*, and I need only say I dealt with it at length there; the experiments referred to being for the benefit of some writers in your contemporary who missed the point at issue.

I also then thanked Mr. Golwey for the information about a machine in Ireland, constructed for Mr. Shaw; but stated that the old specifications of Newton and others he referred to had been long known to me, and did not represent the machines at present in the market.

Yours, &c.,

J. J. COLEMAN.

45, West Nile-street, Glasgow, January 3, 1882.

THE INDIAN PUBLIC WORKS DEPARTMENT.

TO THE EDITOR OF ENGINEERING.

SIR,—Your articles in defence of the civil engineers of the Indian Public Works Department against the unfounded aspersions of the Duke of Argyll deserve our very best thanks. Will you allow one of them to ask, through you, the Council of the Institution of Civil Engineers the reason of their silence on the matter hitherto? I have heard it bitterly commented on more than once. There are by the last classified Public Works list no less than 50 members and 91 associate members of the Institution in the Public Works Department.

The Council represents the profession to us and to the world at large. Was it not therefore their bounden duty to request the present Secretary of State for India to explain the disgracefully false accusations so publicly made by his predecessor? Surely the honour of the profession demanded no less, and it is as much the duty of the Council to uphold this as to hear papers read at meetings. If not what is the Council for?

Yours faithfully,

M.I.C.E.

[Our correspondent will probably have learnt by this time that the Council of the Institution took prompt action in this matter, and that the Duke of Argyll's apology for the unfounded charge he made against the civil engineers of India, left nothing to be desired.—ED. E.]

ELECTRIC TRANSMISSION OF POWER.

After the uncertain and somewhat contradictory reports that have been afloat as to the results obtained by M. Marcel Desprez, in his experiments on the electrical transmission of power over long distances, the record of two trials made in Paris by M. Tresca, with the co-operation of Dr. Hopkinson, will be welcomed by all who are interested in this important subject. These experiments were made under the most rigid conditions; and the results have been analysed and arranged in such a way as to show the amount of power at each point of the installation, and the loss due to each component of the apparatus. The information thus gained indicates to electricians the exact points at which the loss takes place, and further demonstrates how much of this loss may be avoided by better mechanical arrangements, and how much is inherent to this system of transmission.

The trials were made in the workshops of the Chemin de Fer du Nord on February 11 and 18, and the results were presented to the Académie des Sciences by M. Tresca in two papers, which have since been published in our contemporary *La Lumière Electrique*.

The telegraph wire by which the transmission was effected was 4 millimetres in diameter (No. 9, B.W.G.) and stretched from Paris to Bourget, and back again, a total distance of 17,000 metres (10½ miles); its resistance was 160 ohms. The two machines, the generator and the motor, were placed near together. One pole of the generator was connected to the appropriate pole of the motor through the 17,000 metres of telegraph wire, while the other two poles were connected by a short conductor. The conditions were sensibly the same as those which would have been obtained if the two machines had been placed 8500 metres apart, and connected by a double wire, constituting a main and a return lead.

The generator had its armature constructed upon a peculiar plan, devised by M. Marcel Desprez, with a double bobbin, and was wrapped with wire one millimetre in diameter (No. 19, B.W.G.) The motor was a large Gramme machine of the military type, modified for the object in view. The resistances of the two machines were 56 and 83 ohms respectively.

In each experiment the rates of revolution of both machines were determined simultaneously by means of special counters. All the electrical measurements were made by Dr. Hopkinson, F.R.S., with the apparatus of Sir William Thomson. They coincided very exactly with determinations made the preceding days by M. Desprez with his own instruments. The difference of potential between the poles of each machine was taken by a Thomson galvanometer, by aid of a supplementary resistance of 50,000 ohms. The current was measured by means of another Thomson galvanometer, through which the entire current passed. The magnets of both instruments, after having been verified in London on the 9th of February, were examined again on the 13th, on their return to Paris, without any change being discovered. Each division of the galvanometer used to determine the potential, corresponded to 50.7 volts, and each division of the current galvanometer to 0.223 ampère.

The power dynamometer was of the Morin type, and was lent by the Conservatoire des Arts et Métiers. Its indications were given in the form of a diagram. The power exerted by the motor machine was absorbed by a Prony brake, the lever of which, measured horizontally, was 0.796 metres, corresponding to a distance of 5 metres per revolution. The lever was uniformly weighted to 5 kilos., hence the work done per revolution equalled 25 kilogrammetres.

Seven successive trials were made under the above conditions; one diagram, that of the last of these experiments, was a failure. Besides these, in the eighth dynamometric determination, the work consumed in the mechanical transmission, between the dynamometer and the generator, was estimated. The speed was at that time greater than during the other trials, but as the power consumed per revolution formed the basis of the calculation, it was possible to calculate its influence readily upon each of the preceding experiments.

The following Table shows all the data obtained, and also their mean values:

TABLE I.

VIII.	0.78	112	33.6	0.45								

The mechanical work is estimated in French horse-power, of the value of 75 kilogrammetres per second, but the electrical work was calculated by Dr. Hopkinson in English horse-power, at the rate of 76 kilogrammetres per second. The experimentalists have thought it better to publish the Table as it stands than to alter Dr. Hopkinson's figures.

From a consideration of the first six experiments, which are the only ones that are complete, it is seen that out of 6.2 horse-power expended upon the shaft of the dynamometer, there were transmitted 2.03 horse-power, a return of 33.7 per cent. This result is abundantly confirmed by a comparative examination of the successive figures of each of the columns. For a mean velocity 91.2 revolutions per minute of the dynamometer, the work of the mechanical transmission, including the work of the generator when it was running idle, amounted to 0.3 × 91.2 = 28.26 kilogrammetres, or 0.377 horse-power, and the foregoing figure of efficiency is thus altered in the ratio of 2.01 : (6.21 — 0.38) = 34.5 per cent. But little importance is to be attached to this correction, because it is hardly possible in actual practice to suppress this supplementary work, which must include at least the mechanical resistance of the spindle of the generator.

But it is above all in an examination of the efficiency of the individual parts of the installation that the most interesting indications are to be found. In Table II. these points are more clearly to be seen by the dissection of each of the experiments into three distinct parts.

placed parallel with the preceding, the following indications are all that are available:

Electric work of the generator...	...	4.61
Intermediate loss (by difference)	...	1.31
Electric work of the motor	...	3.30
Intermediate loss (by difference)	...	0.51
Actual work transmitted	...	2.79
Efficiency of the circuit	...	0.711
" " the motor	...	0.845

The figure of this last efficiency differs notably from those that are contained in the general Table, but it is not too hazardous to conclude from the ratio 0.711 that the proportion of work transmitted favoured by the notable increase of speed, would not differ greatly from those which were measured directly.

Commencing with the resistances of the two machines in a state of rest it is easy to calculate the work lost in heat, and to deduce by subtraction for each machine, the supplementary work lost either by sparking or friction, or by a possible increase of resistance during working. These losses amounted to .92 horse-power for the generator and .38 horse-power for the motor. This difference is explained by the relative smallness of the work which is put in operation in the motor, and its measure, completing the facts which have been already given concerning the various losses, takes account of all the practical conditions of the trials.

In conclusion, the work actually transmitted to a distance of 8½ kilometres (5¼ miles) by an ordinary telegraphic wire of 4 mm. in diameter (8 B.W.G.) in an installation of the kind adopted by M. Deprez represents one-third of the motive power. If the

" installation	0.348	0.318	0.317	0.326	0.302	0.348	1.959	0.326

The results may be expressed in an extremely simple manner, by saying that each of the three parts of the installation gives a useful effect of about 70 per cent. The resistances of the generator, the heat there developed, the losses by the brushes, and the sparking represent an expenditure of energy equal to 30 per cent. Under the conditions of the trial the heat developed in the circuit represented 30 per cent. of the electrical energy delivered to it. Lest it should be feared that there was some unintentional communication between the two wires, they were carried upon posts all their length, and it is to be noticed that the mean intermediate loss, between the generator and the motor, is equal to 122 kilogrammetres, which corresponds to the total resistance of the circuit, which was 160 ohms. Then the resistance of the motor, including the influence of the brushes, and the sparking, absorbed also 30 per cent. of the electrical energy imparted to it. In round numbers the useful effect differed little from $0.70^3 = 0.343$.

In the data of the seventh trial, which may be

resistance of the intermediate circuit be abstracted, the current remaining unchanged, the corresponding useful effect would amount, according to these calculations, to nearly one-half the motive power. The experiment, which was carried out with the greatest accuracy in all its details, has realised for the first time the transport to a great distance of 2 horse-power, and in one of these trials of 2.79 horse-power.

(*To be continued*).

ELECTRIC LIGHTING NOTES.

THE town of Szegel, in Hungary (70,000 inhabitants), has been partly lighted with incandescence lamps by Messrs. Ganz and Co. The first installation is in the street leading to the railway station, which has been furnished for a length of about 1000 yards with incandescence lamps of about 20 candles, spread at intervals of 40 yards. In the Place at the end of the street are placed four arc lamps.

After a sharp competition Messrs. Siemens Brothers have obtained the order for the electric lighting of the s.s. Aurania, the new boat of the Cunard Line. The success of the installations on the Arizona and the Alaska has been so decided that the Cunard Company has decided to adopt Messrs. Siemens Brothers' system in its entirety, including the rope transmission, instead of obtaining their machinery through intermediate companies, as in the case of the Servia.

A contract has been concluded with the United States Illuminating Company for lighting the great suspension bridge over the East River between Brooklyn and New York. The work will include the installation of 70 arc lamps, arranged on each side of the bridge. The power station will be placed on the Brooklyn side, and the lamps will be on two independent circuits, so that in case of a breakdown only one-half the lamps would be extinguished. The work has to be completed within two months.

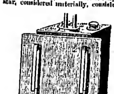
S.S. Tarawera (Union Steamship Company of New Zealand, Limited). The electric lighting plant on board this steamer, which was fitted up with the Edison system, is reported to have worked well throughout the voyage from Greenock to Melbourne. Only ten lamps (out of a total of 150) gave out during the voyage. As the loss of lamps during the first few weeks after starting an installation generally averages higher than that which occurs after the plant has been in use for a short period (owing to the weeding out of defective lamps), the result stated above may be reckoned as very satisfactory.

The Edison system appears to be progressing favourably in Paris. Among new installations there are the feather factory of M. Lodié, with 48 lamps; the glass works of M. Pochet, 20 lamps, and the artificial-flower factory of M. C. Marchais. At the Magazin du Louvre there are 60, at M. Lahure, printer, 60, and at MM. Hachette and Co., publishers, 100 incandescence Edison lamps. In Vienna two large saloons of the Palace of Schönbrunn are to be lighted; in Brussels the theatre in the Park; in Germany the Royal Court Theatre of Dresden, and the Theatre Royal Munich are to be illuminated by the same system.

The American Electric and Illuminating Company of Boston, which commenced its operation in September last, is now working installations of 200 arc lamps, and has orders for 100 in addition. Its central station is situated in the basement of the Massachusetts Charitable Institution, and comprises one 150 horse-power Wheelock engine, two 50 horse-power Lawrence engines, and two rotary engines, one of 30 and one of 100 horse-power. The Thomson and Houston system of lighting is used, and the total capacity of the company's station is 1000 lamps of 2000 candles each. The *Boston Advertiser* states that there are at present over 75,000 arc lamps in use in the United States.

The advent of the Brush storage battery appears to have led to the formation of an alliance between the Brush and Swan companies in New York. There are already 18,000 Brush arc lamps in the United States, and nearly 100 companies, with a total capital of seven million dollars, have been founded in various cities and towns to furnish electric light as a legitimate business. By aid of Mr. Brush's late invention it is anticipated that most of them will be able to greatly increase their operations, and in addition to lighting the streets in the evening, they will be at work all the remaining hours charging accumulators placed in private houses and employed for feeding incandescence lamps.

In the last act of Iolanthe, at the Savoy Theatre there glows upon the heads of every peri, and also upon that of every mortal after he has "put on immortality," a brilliant star, in evidence of fairy privilege. Each star, considered materially, consists of a small



incandescence lamp of two or three candle power, connected by flexible conductors to a secondary battery attached to the back of the wearer and concealed, either by a mass of hair, or by a pair of wings. One of these batteries is shown in the accompanying view, where it will be seen to consist of a gutta-percha box,

considerable than in the first series of trials; the belts had been taken up and were too tight. Each revolution of the dynamometer corresponded to a work of 0.0172 horse-power, whereas it was before 0.004 horse-power. From whatever it resulted this work of 2.196 horse-power included the resistances of all the straps, those of the countershaft, as well as those of the shaft of the generator and of the friction of its bearings. Even if some magnetism existed, or were produced while running empty, its resistance would also be registered. From the point of view of the calculation of the electrical work, and the successive losses which result, it was essential to work out the figures for that loss in the transmission. This reduction made from the motive power, the available power is found to be reduced to 8.193 horse-power out of 10.389, or to 78.9 per cent. of its primitive value, measured at the dynamometer. The heat which was produced, at the expense of the motive power, by the passage of the current in the generator, whose resistance at rest and cold was 56 ohms, represents a declension of work of 0.549 horse-power common to all the trials. The experiments show that there is still a supplementary loss of work between that which the generator receives and the dynamic power of the current which it gives to the circuit. That loss amounted to 0.844 horse-power on the average, and represented all that which had not been taken account of in the calculated value of the heat developed in the generator. What were the exact causes of this difference it is difficult to say; whether the resistance of the machine is greater when working with a closed than an interrupted circuit; to what extent the brushes fail to conduct the current; what is the loss by sparking; and whether counter currents are produced which augment the resistance, are questions whose solution must be deferred for the present.

The current, however, which entered the telegraph wire joining the two stations, never represented more than 6.793 horse-power, that is, 65.4 per cent. of the motive power, or 82.9 per cent. of the power imparted to the spindle of the generator. In traversing the wire of 17 kilometres, whose resistance was 160 ohms, the energy transformed into heat represented

$$\frac{2.687^2 \times 160}{g} \text{ kilogrammetres} = 1.570 \text{ H.P.}$$

The mean difference between the terminals of the generator and the motor was found to be only 1.373 horse-power; in view of the small variations of intensity, which it was impossible to measure during the course of the experiments, these two results may be considered concordant, and to them must be added the passive resistances of the shaft of the motor, of which no direct measurement could be obtained by dynamometer diagrams, as in the case of the generator.

The observations made on the motor showed that the current did not represent more than 5.424 horse-power; that is, 52.2 per cent. of the original motive power, or 66.2 per cent. of the mechanical power communicated to the shaft of the generator. The resistance of the motor, 83 ohms when at rest, corresponded to a transformation into heat of 0.828 horse-power, as is shown upon the ninth line of the Table. But this reduction is not nearly equal to the difference between the energy of the current as it leaves the generator, and the work expended in friction by the brake. This difference, which amounts to 1.309 horse-power, may be attributed to the causes alluded to above. This loss appears to have increased in a remarkable manner with the higher electromotive forces of the second series of experiments, and part of that augmentation must be attributed to sparking.

The power measured at the brake represented on an average 3.301 horse-power; that is, 31.8 per cent. of the motive power, or 40.3 per cent. of the power communicated to the spindle of the generator. The amounts of power which reappeared in the form of heat, and were necessarily lost as useful effect, can be summed up as follow:

In the generator		0.549
" intermediate circuit		1.373
" motor		0.814
Total		2.736

This minimum quantity of work represented by the heat is equivalent to 0.263 horse-power of mechanical power expended, or to 0.334 horse-power of work upon the shaft of the generator.

On the other hand the non-calculable losses amount to

At the generator	0.841
" motor	1.309
Total	2.153

which form the 0.207 horse-power of total work, or 0.263 of mechanical work communicated to the shaft of the generator.

These figures may be grouped in another manner, thus:

Work of mechanical transmission ...	0.211
" lost in heat developed by the resistances	0.263
Work lost adventitiously at the points of transference	0.207
Actual work transmitted...	0.318
Total	1.000

The third item in this list is evidently the one upon which the efforts of constructors should be concentrated, and if these causes of loss could be removed, it would be possible to approach, other things being equal, to a maximum efficiency of 50 per cent.

If the Experiments IX. and X. be submitted to the same process of examination the figures are much the same:

Work of mechanical transmission ...	0.209
" lost in dissipated heat	0.250
" lost at the points of transference...	0.212
" actually transmitted	0.314
Total	1.000

Iron - May 23, 1884

THE DESCENT OF ELECTRIC CURRENTS INTO COAL MINES.—At a recent meeting of the members of the Manchester Geological Society, Mr. John Knowles, M.I.C.E., read a paper describing the descent of an electric current into the New Rivin Pit, one of the collieries owned by Messrs. Andrew Knowles & Sons, Limited. During a thunderstorm which took place on February 21 last, a distinct shock was felt in the workings at the New Rivin Pit, Little Lever, near Bolton. The colliery was situate close to Hall Lane, the main road between Moses Gate and Radcliffe, and about three miles from Bolton, the upcast pit being about 30 yards from the road and the downcast 50 yards. The upcast pit was 9 feet in diameter inside the brick work which rose as a chimney about 24 feet above the ground. In this pit there was no winding, but there was one pulley 5 feet in diameter, which stood without rope, to be used with a portable capstan engine in case of emergency. There were also two folding iron doors, which took up a space in the chimney 8 feet high by 5 feet wide. The pit was 97 yards deep. The downcast pit was also 9 feet in diameter and 97 yards deep, with a sump of 14 yards further. In the pit were four iron guides 1½ inch in diameter, and two iron wire ropes between the cages; the former went into the water at the sump, and the latter terminated just below the landing plates. There were also a bell wire of galvanised iron, and 3-inch steam pipes, which were mostly uncovered. The two cages were made of iron, a steel rope being used for one cage and an iron rope for the other. This pit was surrounded with the ordinary cast plates and rails, but there was not any connection with the chimney of the upcast shaft. There were the usual buildings about the pits, viz. engine-house, boilers, and cabins; also a chimney 6 feet square and 20 yards high, but no lightning conductor on it. At the bottom of the downcast pit there were the usual plates and rails, with the steam pipes extending to two engines on the east side and one on the west. Those going eastward were laid up a brow, with a gradient of one in three, to the Lower Three Yards Mine, and then a short distance on a level to the first engine, which wound up the down-brow in this mine. At this point there was a rise tunnel to the Lower Yard Mine, worked as a self-acting incline. The steam pipes were carried to the top of this tunnel and then on a short level to the engine at the top of a down-brow in the Yard coal, where a wire rope was used to wind the coal to that point. There was also a wire rope used in that brow to work a small pump, which forced water to the top of the incline, whence it ran to the pit. On the west side the steam pipes were laid on a level in the Lower Yard Mine to a small engine, which wound coal up a dip tunnel from the Lower Three Yards Mine. This engine had a 9-inch cylinder with 10-inch stroke, the dip tunnel being 48 yards long, with a gradient of one in five. The electric current appeared to have struck the chimney at the top of the upcast pit about 2.30 p.m. on the day named. It displaced a large quantity of brickwork, and then came down outside the chimney, striking the ground close to it and making a large hole. It then went along the ground to the cast plates at the top of the downcast pit, and it was presumed went down the steam pipes and so into the workings—on the east side going through the Yard down-brow engine and along the rope to the waggons, and on the west side passing along the pipes to the engine where the manager was standing. The strength of the current must have been very great as experienced by a waggoner seated four or five yards from the bottom of the downcast, as he stated that he saw a brilliant flash and heard a great noise, which sounded as if in the pit. He had the heel of his clog on one of the plates at the time, and felt a tingling sensation in his leg which lasted a day or two, and the sole of his clog was burnt as if hot iron had been drawn over it. Other men in the pit also experienced a sensation which they described as resembling the shock received at an electrifying machine. The manager, who was on the west side in the Lower Yard Mine at a small engine 300 yards from the pit, had his hand on the steam handle and felt a shock which numbed him for a few seconds so that he could not see or move, and afterwards was so completely prostrated by the effects of the shock that he was confined at home to bed for six days before he was able to get up and walk. From the statements which had been made by the men, it would appear that there must have been a very strong current of electricity passing down the ironwork of the pit, and it was fortunate that much of it was distributed before it reached the workmen in contact with any metal. The manager, being the nearest in direct contact, seemed to have suffered the most, as the waggoner was only connected with the plates by a wooden clog, and others at the bottom of the Lower Yard coal incline only received a shock after it had passed many means of distribution. Two other cases of a similar kind had occurred, one at the Tanfield Moor Colliery on July 12, 1880, on which a paper was read before the members of the North of England Institute of Mining and Mechanical Engineers, and the other at West Thornley Colliery on December 11, 1883, with regard to which a paper was also read before the same society. Mr. J. Dickinson said he had investigated the matter referred to by Mr. Knowles, and it had occurred to him that the flash had gone down both shafts, although it was only upon the chimney of the upcast that there were the marks of the electric current. Mr. Burrows briefly described a similar incident that had occurred at one of their collieries, and which produced the impression that the pit had "fired." Mr. Dickinson remarked that the descent of an electric current had been given as one explanation of the Risca explosion, which occurred when a violent thunderstorm was going on. In fact, some persons in the district held a very strong opinion that the explosion had been caused by a flash of lightning going down the pit.

The Iron Age - Apr. 25/84

Heat Due to Electric Currents.

An interesting paper on the heating effects of electric currents has been communicated to the Royal Society by Mr. W. H. Preece. With bare platinum wires of small diameter, the general law governing the ratio between the current strength and the diameter of the wire, when the latter is raised to a definite temperature, and where radiation is free, appears from Joule's law to be that the current should vary as the diameter × √diameter or $c = d\sqrt{d}$. Both the results of Mr. Preece's experiments tend to show that the current varies as the diameter. Platinum wires are, however, liable to flaws which practically reduce their effective diameter. Mr. Preece has also determined the strength of currents which produce self-luminosity in wires of different kinds and sizes. These currents were measured by finding the difference of potential at the ends of a thick German-silver wire, whose resistance was .0457 ohms inserted in the circuit. The results with copper, Swedish wrought-iron, German-silver and platinum wires showed that the law $c = d\sqrt{d}$ held very well for all these wires except with those of platinum, the point of low red heat being taken as the fiducial point. The temperature of a wire which becomes self-luminous has been given by Draper as 977° F., and by Daniell as 980° F. The exception in the case of platinum may account for its exception to the law in the former experiments. Mr. Preece infers from his experiments that electric-light wires should be made large enough to avoid the possibility of heating them above normal temperatures; otherwise, points of danger are easily reached by increments of currents.

Engineering, April 83.

THE ELECTRIC TRANSMISSION OF POWER.

On pages 264 and 289 *ante* we gave an account of the results of two experiments in the electric transmission of power, which has been carried out in Paris by M. Tresca, with the co-operation of Dr. Hopkinson. The trials, which were made with the apparatus of M. Marcel Deprez, were described by M. Tresca to the Académie des Sciences, who appointed a commission, consisting of MM. Bertrand, Tresca, Ferd. de Lesseps, C. de Freycinet, and Cornu, to whom it assigned the task of repeating and extending the experiments, so that the accuracy of the conclusions already attained might be officially verified.

The disposition of the machines was the same as on the previous occasions, that is, two of their poles were joined by a telegraph wire 17,000 metres in length, and the other two by a short conductor of inconsiderable resistance. The results of the experiments, measured dynamometrically, are given in Table I., where it will be noticed that the tests numbered I. and II. differ so greatly from the others that there is good reason to assume that the brake became disarranged in some way. The Table, however, shows that 4½ horse-power were transmitted through a resistance of 160 ohms, while the net return was 37½ per cent. of the power expended, the gross return rising, in one instance, as high as 48 per cent. The figures appear to demonstrate that the amount of work transmitted went on increasing with the speed of the machines up to about 850 revolutions of the generator, at which point it was at a maximum. This was probably due to the construction of the machine, which suffered from excessive sparking at that velocity, and often had its commutator surrounded by a ring of fire. It was the opinion of M. Deprez that if both machines had been of the kind employed for the motor, a better return would have been attained.

Table II. gives the electric results arrived at.

The last column shows the proportion of total electromotive forces $\left(\frac{e}{E}\right)$ developed in each machine. The electric return is notably higher than the dynamometrical one, because the electrical energy created in each machine is inferior to the energy expended in the operation. If H be the coefficient of transformation for the generator, and k that for the motor at their respective speeds, then the dynamometrical return is

$$\frac{T_n}{T_m} = \frac{e}{E} k H$$

where T_m is the power transmitted to the generator, and T_n that obtained from the motor. The machines examined by the Commission had an efficiency of 87 and 81 per cent. respectively, which is lower than that of many dynamos, but it must be remembered that they are designed to give a very high electromotive force and but a feeble current.

The experiments show that the best returns to be obtained from this particular installation, from a gross expenditure of 9.514 horse-power at the generator is 3.572 horse-power received at the brake of the motor, or 37.5 per cent., while, considered electrically, the best return is 71.7 per cent.

NOTES.

facing the iron, and then the amount that is wasted in soldering the joints, not less than a quarter of a pound of the metal it is stated being used over one joint, and by the time the iron reaches the man at the top of a high pole or on a building it has cooled down, and has hardly retained sufficient heat to make a thorough joint, hence the slipping of these joints during contraction of the wires, more especially during winter time. Moreover the present irons are so small, they are generally made red hot when required a short distance from the centre of operation, and the wire naturally becomes brittle from overheating. Hence numerous breakdowns, leaving out the risk of fires where the iron has to be hauled up on roofs, whereas, as mentioned, this iron will retain sufficient heat to thoroughly solder eight or more joints without risk of fire. The flat or other side of the iron may be used for ordinary soldering purposes. On this side also there is a small groove, to allow of the waste solder to run into the cylinder, I C.

We understand that this iron will be made in various sizes, to suit large or small gauge wires or cable work.

THE ELECTRICAL TRANSMISSION AND STORAGE OF POWER.*

By Dr. C. WILLIAM SIEMENS, F.R.S., M. Inst. C.E.

[At the time Dr. Siemens' paper was read we gave a brief abstract of the same, and we have now the pleasure of presenting this discourse to our readers in its entirety.—Eds. Elec. Rev.]

Mr. President, Colleagues, and Gentlemen,—If I interpret rightly the intention of your Council, it was not that these lectures should be what may be called popular lectures, or appeals to mere amateurs interested in the subject; nor do I understand that it was their intention that they should be strictly scientific lectures, such as would deal with ultimate laws and formulæ, or such other information as might be found in text books; but I presume the intention was that those members of your body who have given thought and study, and also attained experience in particular branches of engineering, should communicate their knowledge to their colleagues, having regard particularly to the younger members of the profession.

The general subject that has been selected for the present session is electricity—the most subtle of the forces of nature which it is the business of the civil engineer, according to the terms of our charter, to direct. The two lectures preceding this have been devoted to the action of electricity when it is a swift agent, carrying our thoughts to distances only limited by geographical bounds. The first lecture, by Mr. Preece, dealt with telegraphy; the second, by Sir Frederick Bramwell, was upon that branch of telegraphy (for so I must call it)—telephony, which accomplishes the wonderful feat of communicating speech to reasonable distances. In both cases the receiving instrument is of the most delicate nature that the ingenuity of engineers has been able to contrive for recording the small efforts of energy flowing through the wire. The task that has been assigned to me is to introduce electricity to you, still as a precise and swift agent, but as one that can moreover accomplish quantitative effects, rivalling those produced by our steam-engines, by our hydraulic accumulators, and by compressed air. It is with reference to electricity in this form that I propose to put certain experiments and explanations before you.

Electricity, as you know, is the youngest form of energy with which we are practically acquainted. Although the only available source of that energy was until lately the galvanic battery, attempts were made, from the days of Volta, at the beginning of the present century, to apply that force for the obtaining and transmitting of power. A very little consideration will convince us that all those efforts must necessarily have been futile. A pound of zinc is produced by the combustion of from 15 to 20 pounds of coal, and while a pound of coal in burning gives out 12,000 heat units, a pound of zinc in burning gives only 2,340. Thus zinc gives in burning only one-fifth of the effect in energy that coal does, and taking the cost of zinc at 50 times that of coal, it follows that the cost of energy, in the case of a galvanic battery, is, roughly speaking, 250 times greater than in a steam-boiler. Thus handicapped, it was not likely that electricity could be made available for producing powerful effects, although the attempts that were made—in ignorance of the laws of nature governing the force of electricity—were numerous.

Before entering upon the most essential part of my subject, I must mention an invention or discovery of Seebeck in 1822—that of the thermo-battery. I have here a thermo-battery in which the heating agent is gas, which we will have lighted, and you will see that from it proceeds a current, exceedingly weak, yet a current which owes its origin entirely to heat; and by it we can effect transmutation, so to speak, of heat energy into electrical energy, without any intermediate mechanism or contrivance. If alternate strips of metal, of different positions in the thermo-electrical scale, such as bismuth and antimony, are joined at the ends into couples, and one point of juncture is heated while the next is kept cool, a current is set up, flowing from the hot to the cold juncture, and the moving power of the current thus produced is proportionate to the difference of temperature between the hot juncture and the cold, and to the relative positions of the two metals in the thermo-electric scale. If this transformation could be affected without loss, we might hope that the thermo-battery would be the ultimate and most perfect solution of the problem of developing electric energy out of heat. Sir William Armstrong, in his inaugural address at York in 1881, as President of the Mechanical Section of the British Association, drew particular attention to the thermo-battery, as one of the most hopeful sources of ultimate electrical effect, and physical experimentalists should never lose sight of this interesting problem. Yet the thermo-battery has one drawback, in common with the steam-engine or any thermo-motor—that is, it is dependent, not only on the first law of thermo-dynamics, according to which heat is changed entirely into its equivalent of electricity, but also on the second law, which says that whenever such conversion of heat takes place, a certain amount of heat must descend from a point of high-potential to a point of low-potential. It is thus that our best steam-engines give in mechanical force only about one-seventh of the theoretical equivalent of the heat-energy; and it is owing to this second law of thermo-dynamics that there must be necessarily a loss of heat, by conduction in the metal strips themselves, which conducted heat must be abstracted at the cooled extremities all round, in order to keep up the extremes of temperature upon which the action of the thermo-battery depends. We will now see whether we can produce a visible effect by the current on the electro-dynamometer, an instrument the nature of which I shall have occasion to describe hereafter. The action is not great, but you see that there is a very decided deflection to this side of about 5 degrees. The battery has not been on long, or it would probably amount to 10 degrees. From measurements which I have only lately made at leisure, I find that it would require one thousand eight hundred single pairs of these strips to produce a potential sufficient to work an incandescent electric light, showing how very slight the current really is.

I now approach a subject in our lecture which is of the greatest importance. I have here the original magnet, and the original coil, which Faraday used in the year 1831—fifty-two years ago—to develop the first induction spark. In 1826, or 1827, he had already conceived the idea that when an armature was removed forcibly from a permanent magnet, the expenditure of force should give rise to a current in the wire surrounding the armature; but it took him three or four years to develop the idea. When Faraday saw the spark

* Institution of Civil Engineers, March 16th, 1883.

and was able to show it to the members of the Royal Institution, it was a red-letter day in his existence, and he even then thought that it would be a point of departure of some importance, because he said on that occasion: "Although this spark is very small, so that you can hardly perceive it, others will follow who will make this power available for very important purposes." Now that the light is lowered, I will draw your attention to the point of the wire touching this little disk or pan, and you will distinctly observe the spark when I break the connection. This magnet is the very steel magnet which Faraday used, and at that time it was quite a giant amongst magnets.

Faraday next turned his attention to magneto-electricity, and to what was called by him the magnetic field. I have here a horse-shoe electro-magnet, with its two stems surrounded by coils of wire. If a current is passed through the coils, these extensions become magnetic poles, and if I lay a piece of cardboard upon them, and spread over it some iron-filings, you will observe that, under the influence of the electric current, they distribute themselves in a very peculiar way. Most of the iron filings you see have massed upon two spots, exactly corresponding to the two poles; and all round these spots, lines which are called the lines of magnetic force are shown by the iron filings. It is, of course, difficult, in an experiment of this sort, to show the action as completely as one can in a laboratory; I have accordingly brought some photographed cards, which are certainly very instructive. In these the result of the attraction of the poles, the outflowing lines, as it were, of force from the magnet running in all directions, are well depicted. In the one that has been reproduced, in fig. 1, the two half-circles, intensely white, are the magnetic fields of a dynamo-machine such as you see before you, and the diagram enables us to trace the intensity and direction of the magnetic action in every part of the machine.

Now if a wire forming a closed circuit was taken across these lines of force, although passing only through air (indeed it might be passing through a vacuum), it would encounter resistance due to the magnetism, and this resistance manifests itself as a current of electricity passing through the wire. I shall endeavour to make the experiment in such a way as to render this action visible to you. I have here my magnetic field, that is to say, two polar surfaces opposed to one another, and a framework wound six times round and round with wire; a single wind would do, but by winding six times I repeat the action which would take place upon the one wire sixfold, and this action I expect will be manifested upon a galvanometer-needle with which this frame is connected. I can move the frame about away from the magnetic field and no action is produced on the needle, but when I move the wires into the magnetic field, there is an action in one direction, and when I move it out again there is an action in the contrary direction. The current produced in this wire is exactly proportionate to the amount of force which I exerted, and this again is proportionate to the rapidity of the motion and to the intensity of the magnetic field. If the two poles are set very close together, and if the current exciting the electro-magnet is great, the current produced in the induction wires will be great also. Again, if I move the wires through the magnetic field with great velocity I encounter greater resistance, and I shall obtain a still greater result. In fine the mechanical power expended in passing the wires through the magnetic field is converted at once into electric power or current.

When the magneto-current had been scientifically proved, it was soon taken advantage of in the construction of the machines of Pixii, of Holmes, and of the Alliance Company, which latter machines were made successful at a very early date in lighting some of the coasts of France, and also of this country. Steel magnets were employed, between the poles of which armatures furnished with coils of insulated wire were made to rotate, when, by the inductive action thus produced, alternating currents were set up in the coils and conveyed to the electric lamp without being changed into a continuous current by means of a commutator.

The next advance upon Faraday's original conception was an armature by which the inductive action can be multiplied considerably. In the Faraday instrument the armature was separated from the magnet by lifting it away from it. In this, which is generally known as the (Werner) Siemens' armature, the coil is put upon an H piece of iron, and made to rotate in a magnetic field. There are in the magneto-machine placed on the table steel magnets superposed one above the other, and between the poles of these magnets such an armature is made to rotate with considerable velocity. You will easily perceive that each time the iron head of the armature is separated from the line of poles of the permanent magnets, *i.e.*, each time it makes a half-revolution there is a severance due to each of these magnets. Therefore, if there are eight bars, we have on the one side of the electro-magnet the joint effect of eight severances, and on the other side a similar amount of effect. So that for each half-revolution we get the result of sixteen such sparks as that shown in Faraday's experiment, and if this can be repeated at a

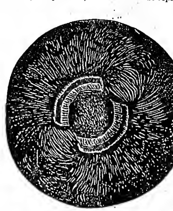

Fig. 1.—Section of Dynamo Machine.

very rapid rate we may get sixteen sparks perhaps ten times in a second. We will now connect the current, not with the dynamometer, because it would not be so suitable, but with one of these instruments which are generally used for exploding mines, and I will, with your permission, explode a mine. Instead of one we might have ten or twelve mine-exploders in a series. You observe a very powerful instantaneous current resulting from the action of the machine.

A further step in the development of magneto-machines was furnished by Mr. Wilde, of Manchester, by substituting for the steel magnets electro-magnets excited by the current from a separate magneto-machine furnished with the Siemens' armature. By this arrangement Mr. Wilde was able to realise much more powerful effects than could have been obtained previously.

Another form in which the Faraday or Induced current manifests itself is in an induction coil, and this also represents an essential action which we should realise before going any further. In an induction coil one spiral of insulated wire is put within another, both upon an iron centre. When a bar of iron is surrounded, as in this instance, with wire, through which a current is passed, the bar becomes a magnet; and if outside the wire of the primary coil, as it is called, fine wire is wound, a current is induced in the secondary coil which is of high potential, or tension, according to the number of turns which the

FACTS NOT GENERALLY KNOWN CONCERNING ELECTRICAL INVENTION.

By J. S. Beeman, M.S.T.E.

The history of the transmission of electric energy by high-tensioned currents, its storage and distribution, is very interesting, as showing the development of an idea which has for long exercised a certain fascination for practical men, viz., the transfer of the energy of waste natural sources of force to localities where it can be utilised. As these localities may be situated at a considerable distance from the source of force, the capital invested in the collecting, transmitting, and distributing apparatus must of necessity be the ruling factor in the case from a commercial point of view, and therefore the economy to be effected by the application of some system for storing the energy and changing its tension to such as is found by experience to be the most expedient, is of great importance. Having in view the improvements in secondary batteries which have already been published, and those which we have still a right to expect, the day may not be far distant when the ideas that have been promulgated regarding such a system, applied to the distribution of electricity, will take concrete form. The various steps by which it has attained its present position, and been brought into the ranks of practically applied natural sciences, form the subject of this article. One of the earliest notices formulating such a design appeared in an article in the *Chemical News* in the year 1862, and ran as follows:—"Sitting by the seashore a few days since, we could not help noticing the vast reservoir of mechanical power existing in the ocean. We do not refer to the noisy dash of the waves as they break upon the beach, but to the infinitely mightier although silent and progressive energy exerted in the gradual rise and fall of the tides. By means of appropriate machinery connected with this tidal movement, any kind of work could be readily performed. Water could be pumped or air compressed to any desired extent, so as to accumulate power for future use, or for transport to distant stations. Light of surpassing splendour could be generated by means of magneto-electric machines; and with a very little extension of ingenuity, every lighthouse on the coast could be illuminated with sun-like brilliancy and with absolutely no expenditure of fuel; the very same mechanical power of the ocean, which in its brute force would dash the helpless vessel to pieces against the rocks, being bound and coerced like the genii in Eastern tales, and transformed by man's intellect into a luminous beacon to warn the mariner against the approach of danger." This idea of utilising the tidal power was, in 1871, actually embodied in a patent by Ferdinando Tommasi, for the working of which it was proposed to form a company. The apparatus, called the flux-motor, was a machine worked by the action of the tides, by which compressed air was to be delivered to customers through a network of pipes, on lines somewhat similar to those employed for the supply of gas. The idea was certainly somewhat unique, but, as far as can be ascertained, has never been practically tried; had it been carried to a practical commercial issue we should by this time have been in possession of a very cheap source of power for the production of electric energy. The possible application of this great natural force, by enclosing tidal waters just before the ebb sets in, and working motors through their release, has, however, been shown, in most cases, to be probably less remunerative than the utilisation of the land so enclosed for other purposes. In 1877 public attention was drawn to this question by the late Sir W. Siemens in his opening presidential address to the Iron and Steel Institute. He then stated that the energy of the Falls of Niagara might be made available by the then known mechanical means—though undoubtedly in a very wasteful manner—saying, to quote his own words, "Time will probably reveal to us effectual means of carrying power to great distances, but I cannot refrain from alluding to one which is, in my opinion, worthy of consideration—namely, the electrical conductor. Suppose water power to be employed to give motion to a dynamo-electrical machine, a very powerful electrical current will be the result, which may be carried to a great distance through a large metallic conductor, and then be made to impart motion to electro-magnetic engines, and ignite the carbon points of electric lamps, or to effect the separation of metals from their combinations. A copper rod, 3in. in diameter, would be capable of transmitting 1000-horse power a distance of, say, thirty miles; an amount sufficient to supply a quarter of a million candle-power, which would suffice to illuminate a moderately sized town." It is of historical interest that in the following year—1878—Sir Wm. Armstrong practically applied this method for the utilisation of natural forces in lighting his house at Craigside during the night, and working his lathe and saw bench during the day, by power transmitted through a wire from a waterfall nearly a mile distant from his mansion. In October, 1878, Mr. St. George Lane Fox patented his system for electric distribution by means of secondary batteries, and, as far as information is obtainable, this is the first public mention of secondary batteries being employed in such a system, although, as has been shown in a previous article, they had been patented at an earlier date as regulators to the circuit. Mr. Lane Fox's system is an extension of the idea of regulation, and it is worthy of passing note that at this period high-tensioned current dynamos, such as we are now accustomed to—the Brush, for instance—were practically unknown, the Brush patent not then having been published in this country. In November of the same year, a French engineer patented an invention, entitled "Improved means of Transmitting Electricity to Great Distances." Although his views and ideas were erroneous, the patent is interesting as showing that inventive talent was directed towards the subject of this paper, and because of the crude ideas contained in it as to the character of dynamic electricity. In December, 1878, Edison patented a system showing duplicate sets of batteries, one set being in the discharging circuit whilst the other could be in the charging circuit—there was practically no difference of tension in the two circuits. An interesting part in the patent was the apparatus whereby the sets of batteries, when fully charged, were cut out of the charging circuit; this was effected by utilising the gas given off to lift a diaphragm which actuated a switch or contact breaker. In May, 1879, Sir William Thomson gave evidence before the Select Committee of the House of Commons on lighting by electricity, saying, in reference to the utilisation of the energy of the Falls of Niagara for the purpose of generating electricity, and in answer to question No. 1799, "There is no limit to the application of it on a general scale. It might do all the work that can be done by steam engines;" he qualified this, and explained how it could be done in a later part of his evidence, by stating, in answer to question No. 1903, that the current sent along the wire would be used to turn electro-magneto machines, which current would be produced by magneto-electric machines. In October, 1879, Lake took out a patent for Houston and Thomson, wherein they showed means by which the tension of the discharging circuit might be raised far in excess of the tension of the current produced by the generator, this being accomplished by charging the batteries in sections and discharging them in series. The special feature of the patent bearing on our subject is contained in the twenty-second claim, and is the method described of bringing a dynamo-electric machine into circuit with a storage battery by first bringing the machine to its normal condition of working by the interposition in its circuit of, first, a normal working resistance, and afterwards of the secondary battery. In March, 1881, Professor Perry, whilst lecturing at the Society of Arts, said that for the future development of the transmission and distribution of electric energy it would be necessary to use electric machines of great electro-motive force. During the lecture, and afterwards in the discussion, reference was made to Professor Ayrton's paper read at the British Association meeting, held the previous year at Sheffield, wherein he pointed out, in a full and comprehensive way, how the energy of the Falls of Niagara might, theoretically speaking, be conveyed to New York along a single ordinary telegraph wire. The system, which was based on theoretical grounds only, and was dependent on exceptionally good insulation, was explained thus: Only a small amount of current would be conveyed along the wire, but it would have an enormous potential; and although the difference of potential between the ends of the telegraph wire would be nearly *nil*, yet the difference of potential at all points along the route, between the line wire and the earth, would be extremely large, so that much energy could be put in at the generating place—viz., Niagara—and a nearly equal amount would be delivered at the motor place—viz., New York. Thus, through the current being so very small the waste of energy in electric friction would be very slight. In April St. George Lane Fox, when lecturing before the Society of Telegraph Engineers, carried the system a step further by expounding a scheme whereby the energy transmitted under high potentials could be safely and usefully applied. He is reported to have used the following words:—"Electricity could be conveyed from a very great distance at an enormous electro-motive force, which electro-motive force could be reduced to any extent by means of a system of condensers, or of secondary batteries, and a suitable arrangement of commutators working automatically, so as to suit the requirements for distribution." Mr. Crompton, during the discussion, said: "As to the use of the secondary or reservoir batteries to act as a store of electrical energy, it is one of those things much talked of, but never yet practically carried out. M. de Meritens told me a few days since that a secondary battery had been recently brought out in France, which gave surprising results; five or six times as much energy can be stored in it as in the Planté battery." About May 16th appeared a letter in the *Times*, announcing the arrival of the above secondary battery, called, after its inventor, the Faure accumulator. On May 18th, Mr. Alexander Siemens lectured at the Society of Arts upon "Electric Railways and Transmission of Power by Electricity." He described a number of ways in which high potential currents could be utilised. He drew attention to large central stations fitted with powerful steam engines and dynamos supplying current to secondary batteries which would keep the electric energy stored until required for use. On June 6th appeared the celebrated letter of Sir William Thomson anent the Faure secondary battery, in which he stated that "the Faure accumulator always kept charged from the engine by the house supply wire, with a proper automatic stop to check the supply when the accumulator is full, will be always ready at any hour of the day or night to give whatever light is required." On the 9th he further wrote, when alluding to credit due to the late Sir William Siemens as the originator of the idea of utilising the Niagara Falls as the natural and proper chief motor for the whole of the North American Continent, "Under practically realisable conditions of intensity, a copper wire of ½in. diameter would suffice to take 26,500-horse power from water-wheels driven by the Fall—losing only 20 per cent. on the way—to yield 21,000-horse power at a distance of 300 British statute miles; the prime cost of the copper amounting to £60,000, or less than £3 per horse-power actually yielded at the distant station." Early in September he, when delivering his opening address as president of the Physical Science Section of the British Association at the York meeting, went still further, and pointed out that through the introduction of accumulators much smaller conductors could be used than were anticipated by the late Sir William Siemens in 1877, and, further, that the necessarily high potential current employed to transmit the current long distances could be converted at its centre of distribution into such a low potential current as should be desired for the several purposes at the points of consumption of the electric energy. He went into fuller details regarding the contents of the letter alluded to above, stating that until he heard of Faure's invention he could only think of step-down dynamos at a main receiving station, to take the energy direct from the electric main with its 64,000 volts, and supply it by secondary 200 volt dynamos through proper distributing wires to the houses and factories and other places, where it could be used for every suitable purpose requiring power. Now the thing could be done much more economically and with much greater facility and regularity by keeping, say, 40,000 secondary battery cells always being charged direct from the supply main, and applying a methodical system of removing sets of 100, and placing them on the town supply circuits, while other sets of 100 were being regularly introduced into the great battery that is being charged. He further described and showed an automatic apparatus which he had designed and constructed to break and make the circuit between the battery and the dynamo. On the 21th of September, Duprez and Carpentier obtained a patent, wherein was described a system very similar, but, of course, giving more definite details of apparatus to be employed than did Sir William Thomson in the address referred to above. They referred to an automatic galvanometer which actuated a commutator or switch, thus causing the connection of the discharging circuit to be always in contact with a very constant supply of electricity. In November Professor Sylvanus Thompson, at a lecture at the Society of Arts, stated that we had in the tidal basin of the Avon enough energy to light Bristol, and in the channel of the Severn there was sufficient power—if only one-tenth were conserved in accumulators—to drive every loom spindle and axle in Great Britain. By this time the inventive public was thoroughly aroused, and the records of the Patent-office show that the details of the working out of the above system have received great attention. Nothing new has, however, been shown affecting the principle. Last month news reached this country that the Bell Telephone Company has two wires connected with the Niagara Falls, by means of which the Exchange at Buffalo has recently been operated. As an experiment, a generator was placed on the paper mills of Quinby and Co., at Niagara Falls, and the machinery connected with twenty miles of wire, the result being a success. The various attempts that have been made in this and other countries, notably France, with systems worked on the lines herein set forth, are practical evidence of the value of the foresighted idea of the late Sir William Siemens.

Iron — Oct. 10, 1884

97

THE DISTRIBUTION OF ELECTRICITY.

We have from time to time recorded with satisfaction the progress made by the Gaulard-Gibbs method of distributing electrical energy for the production of light and power by means of secondary generators, which system was first described and illustrated in IRON for April 27, 1883. Since that date we have seen it successfully applied on the Metropolitan Railway, where for five months five stations were lighted over a circuit of 15 miles. That installation has now been greatly exceeded by one in connection with the Turin Exhibition, and in which the Gaulard-Gibbs system stands out both prominently and successfully. Before describing this new installation, we may premise that electrical apparatus forms an important feature in the Turin Exhibition. There are in the electrical section several exhibits of the greatest interest, which are shown by firms or companies who have already done good service to science and industry. The Italian Edison Company, of Milan, may be mentioned as exhibiting much that is interesting and excellent. Messrs. Sautter Lemonnier & Co., of Paris, and Messrs. Siemens, of Berlin, stand out conspicuously, but it is the English installation which is the great novelty, and, we may add, the great success of the Turin Exhibition. This, we need hardly say, is the Gaulard-Gibbs system of electrical distribution, which is exhibited by the National Company for the Distribution of Electricity by Secondary Generators, and whose offices are at 18, Warwick Street, Regent Street, London. The Italian government, together with the city of Turin, have offered a prize of 15,000 francs, or £600, for the most important improvement in that department of electrical science, which so closely effects so many branches of industry, namely, the transport of electrical energy over a great distance. The Gaulard-Gibbs system has been in competition for the prize, and has succeeded in carrying off a remarkable share of honours. By this system electrical energy has been transported, and applied to lighting under practical and economical conditions over a much greater distance than has hitherto been done by anyone. The motive power of the National Company and their dynamo (an alternating current machine by Messrs. Siemens Brothers, of London) of 60 horse-power, and supplying a current of 3,000 volts and 10 ampères, being installed within the exhibition, the company undertook to transport electrical energy as far as the railway station of Lanzo, a pretty little town at the foot of the Alps, and at the entrance of the valley of the Stura. The undertaking was a bold one, necessitating complicated details of installation both tedious and difficult. But the great importance of the demonstration was universally realised, as well as its wide interest for a progressive and industrial country, rich in hydraulic power and poor in fuel such as Italy, and everyone sought to aid M. Gaulard in the demonstration which, on behalf of his company, he went to make. The Italian government, the executive committee of the exhibition, the railway company of La Haute Italie and that of Turin-Cirié-Lanzo, the administration of the state telegraphs, the Turin and Lanzo municipalities, all lent their valuable aid, and it must be added to the honour of science that valuable assistance was rendered by electricians who were the first to applaud the progress realised by one of their confrères.

By this installation we have the unprecedented fact of electrical energy furnished by a Siemens machine being transmitted to a distance of 40 kilometres, or 25 miles, from the machine along a single conductor, which forms, consequently, a circuit of twice that length, electrical currents of varying potential being developed at the extremity as well as at several other points of the circuit. This conductor, which was placed at the disposal of M. Gaulard by M. Mouchel, of Paris, is a simple Mouchel bronze wire of 3½ millimetres, or ⅛ inch, in diameter, costing £10 per kilometre, or a little over £16 per mile. This conductor is entirely without insulating covering of any description; and it is worthy of remark that, even in this condition, the heaviest rain does not interfere with the passage of the current. This fact has been thoroughly proved, for the first experiment was conducted during a tropical downpour. The conductor is attached to ordinary insulators on the telegraph posts of the railways of La Haute Italie and of Turin-Cirié-Lanzo. The wire is placed below the telegraph wires, and in returning by the same posts forms a circuit 80 kilometres, or 50 miles, in length, which is metallically closed with the terminals of the dynamo machine at the exhibition. It should be observed that, to keep the conductor at a certain height from the ground, it was found necessary to place the outgoing and returning portions of the conducting wire near together, the distance separating them being only from 20 to 25 centimetres, or 7·874 to 9·842 inches. This primary conductor established, M. Gaulard placed at different points of the circuit secondary generators, the secondary currents from which serve to light glow and arc lamps of various systems, thereby demonstrating with what facility he can arrive at, not only the transmission, but the distribution of electrical energy. In the exhibition building itself, secondary generators of different sizes and patterns supply currents for Siemens and Sun arc lamps, and for Bernstein and Swan glow lamps, the intensity of the light being regulated at will. The kiosque of the *Figaro* newspaper, situated in the park of Valentino, is brilliantly illuminated by a cluster of five Bernstein lamps, fed by a small secondary generator. The station of Turin (one of the termini of the Turin-Cirié-Lanzo Railway, and which is distant from the dynamo machine in the exhibition 10 kilometres, or 6¼ miles, in consequence of the detour the circuit has to make in following the telegraph posts) is splendidly lighted with eighty-two Edison lamps, which the Italian Edison Company have fitted up at their own expense. These lamps are fed by a secondary generator of four columns, with energy to spare; another small column lights a Siemens arc lamp outside the station. The stations of Venaria, Reale, and Cirié are lighted by Siemens and Cruto lamps. Lastly, the station of Lanzo, distant 32 kilometres, or 20 miles, from that of Turin, is lighted by Swan and Bernstein glow lamps, and by Sun and Siemens arc lamps distributed tastefully over the interior and exterior of the station, and fed by several columns of secondary generators. This point marks the entire length of the little line which it is contemplated to transform into an electric railway, and in doing so to utilise the ample water-power in its neighbourhood.

This installation, complete in all its details, and thoroughly demonstrating the value of the principles advanced by M. Gaulard, and of the apparatus which he has constructed for applying them, was inaugurated on September 29 by the international jury of the electrical section of the Turin Exhibition, and will continue to work on stated days until the end of the present month. That the jury consists of men well calculated to thoroughly test the merits of the system may be gathered from the fact that amongst them are—M. Tresca, member of the Académie des Sciences of Paris, director of the Conservatoire des Arts et Métiers, vice-president of the Société Internationale des Electriciens; M. Wartmann, recteur de l'Université de Genève; Professor Voit, of Munich; Professor Kittler, of Darmstadt; Professor Ferraris, of the Polytechnique of Turin; Commandant Parant, of the Italian Navy; Professor Cossa, of the Ecole des Ingénieurs of Turin; Professor Roiti, of the Ecole Supérieure of Florence; Professor Ferrini, of the Ecole des Ingénieurs of Milan; Professor Webber, of Zurich, Ingénieur Candillero, of Turin, president of the Ecoles Professionnelles; and Captain Pescetta, of the Génie Militaire Italien. Professor Ferraris, the organiser and president of the electrical section, was unanimously chosen by his Italian and foreign colleagues to preside, M. Tresca having been nominated honorary president. It may be mentioned that Professors Voit and Kittler were charged with the duty of taking electrical measurements at the Munich and Vienna electrical

over

exhibitions. To entering upon the work of adjudicating the high prize offered by the government of Italy and the municipality of Turin, the jury commenced by taking electrical measurements by the most exact scientific methods of the effective return obtained from the secondary generators, a question which has already given rise to much discussion, but which has been determined in London by a report of Dr. John Hopkinson. The jury employed the electrometer of Mascart, which is recommended by the highest electrical authorities in Paris. The effective return established by the jury is 90 per cent.; which is even higher than that given by Dr. Hopkinson, and this is attributable to the perfected construction of the secondary generators now employed by Messrs. Gaulard and Gibbs.

To celebrate the advent of the electric light in the Alpine town of Lanzo, and transmitted, too, all the way from Turin, a brilliant fête was organised by the directors of the Turin-Ciriè-Lanzo Railway and by the manufacturers of the valley of the Stura, over which the chairman of the Bank of Turin presided. A special train arrived at Lanzo about seven o'clock on the evening of September 29, conveying the jury and several notabilities of Turin, amongst them being the Count de Sambüy, syndic of Turin and senator; Commander Villa, president of the executive committee of the Turin Exhibition, a member of parliament and formerly minister of justice; the chairman of the Turin-Ciriè-Lanzo Railway, and the rector of Turin University. The guests were received on their arrival at Lanzo by the syndic of that town, the manager of the railway, and several of the most enterprising manufacturers of the valley, amongst whom may be mentioned MM. Remmert Brothers, M. Bona, M. Cardolle, and M. Martiny. With them was the well-known engineer of Milan, M. H. Bellinger, who has erected so many engineering works in the country about Lanzo and in other parts of Piedmont, as well as in Lombardy and Tuscany. A banquet was prepared in the restaurant of the station, and, at the moment of the guests sitting down, M. Gaulard caused the glow lamps to be lighted, and the room was splendidly illuminated. Thus the almost unknown little town of Lanzo witnessed this new advance in conquering science. It is satisfactory to us to be able to state on good authority, though the official announcement has not yet been made, that, as a result of their investigations, the jury have awarded the National Company for the Distribution of Electricity by Secondary Generators the first prize at the Turin Exhibition, which includes £400—out of the £600—placed at their disposal for prizes in the electrical department. Watching as we have, with interest the progress of the system devised by Messrs. Gaulard and Gibbs, we cannot but congratulate them on this excellent result. In the history of the development of electricity and of the progress made in its practical application to everyday wants, the demonstration of Lanzo will certainly always stand out in bold relief.

Iron — Nov. 14, 1883.

THE DISTRIBUTION OF ELECTRICITY.

It is now nearly three years since a vigorous impulse was given to the question of electric lighting. Numerous systems more or less ingenious, for the production and consumption of electricity have been designed. The public, attracted by the real advantages this system of lighting offers, has liberally responded to the invitations made by the several companies which have in some instances somewhat hastily promised the full advantages offered by electricity as an illuminating agent. This wide-spread impulse has necessarily resulted in some remarkable improvements in the art of producing and consuming electrical currents. Further the wonderful process of transforming mechanical power into electricity, and *vice versâ*, has caused the labours of numerous scientists and *savants* to be directed towards the attainment of the means of carrying out this process by the transmission of natural forces and their consequent utilisation. Nevertheless, many false impressions have been produced, and considerable capital has been swallowed up by companies which have no practical vitality, as well as by speculation. But although the production and the consumption of electricity have been rendered possible, the laws which regulate the distribution of electrical currents have presented a problem which hitherto would appear to have remained without practical solution. It is very certain that if the employment of gas had necessitated the manufacture of this illuminating agent on the premises of consumers, its use would have been considerably restricted. In like manner the hitherto existing necessity of placing on or near the premises of consumers the dynamo machines necessary for the production of electricity has considerably cooled the enthusiasm shown by the public in the first moment of excitement.

In our issue of April 27 last, in discussing the recent results obtained by M. Marcel Deprez, and by the secondary generators exhibited by Messrs. Gaulard & Gibbs at the Westminster Aquarium, we defined the conditions under which the solution of the problem of the distribution of electricity could alone be solved. These were—Firstly, that the economical mechanical production of electric currents which, wherever possible, should be produced by utilising natural forces. Secondly, the distribution over great distances, not of an electrical current, but of electrical energy, which is a very different matter, for every given current has special properties, and consumers should not be limited to the employment of special apparatus adapted to the given current, for this would be to discourage improvements in such apparatus. Thirdly, the distribution of electrical energy must be effected without permanent danger to consumers, and as far as possible to an unlimited extent. Lastly, the consumer should be able to transform this electrical energy into currents of every kind, and consequently adapted to every purpose already known or that may hereafter be discovered, amongst the former being lighting by incandescence and by arc voltaic, chemical processes, such as electro-plating, and furnishing motive power. We have now to direct attention to the fact that in principle the secondary generators of Messrs. Gaulard & Gibbs fulfil all these conditions, and it is gratifying to find that after so short an interval our anticipations have been realised. Whilst the path followed by M. Marcel Deprez has led to no further results as regards himself, the National Company for the Distribution of Electricity by Secondary Generators, whose offices are at No. 18, Warwick Street, Regent Street, London, has practically applied its Gaulard-Gibbs system of distribution by means of a single cable twenty-five kilometres in length and four millimetres or one-sixth of an inch in diameter passing through the several stations of the Metropolitan Railway, and enabling the secondary generation of electrical currents at Notting Hill Gate, Edgware Road, Gower Street, King's Cross, and Aldgate. At each of these stations a secondary generator acts under the influence of the movement of the primary alternating current which traverses the primary circuit, metallically closed on the generating dynamo machine, transforming a part of the energy into electrical currents of different kinds which are employed at each station for feeding incandescent and arc lamps, and at one station, we understand, power also. We recently announced the thorough and practical success of this enterprise.

We need not here repeat the theoretical considerations which have been fully discussed in our columns. We wish simply to place before our readers particulars of the apparatus employed by Messrs. Gaulard and Gibbs in the different stations of the Metropolitan Railway, and of which a perspective view is given on page 529 of our present issue. These secondary generators are composed of sixteen vertical and parallel columns placed between two platforms of wood, to which they are individually attached by means of four iron bolts. Each column is formed of a hollow cardboard cylinder 2 inches in diameter, upon which is rolled in two layers of superposed spirals, a cable composed of a central copper wire, No. 8, B. W. G., covered with a double layer of paraffined cotton. Around this central wire are placed, in parallel order and completely enveloping it, six cables individually composed of eight copper wires, No. 26, B. W. G., and similarly insulated by a double layer of paraffined cotton. This arrangement has been adopted by the inventors in order to avoid the inductive reaction which would occur in the spirals of the primary circuit if they were placed next to one another. The columns, in groups of four, are arranged so that the terminals of their inductor are brought to the commutator placed in front of the apparatus, the object of which is to direct the primary current by one or more of these groups of columns. The terminals of the secondary wires are themselves conducted to four circular commutators of identical construction placed on the side of the apparatus, the object of which is to couple these terminals by means of a simple handle either in parallel order or end to end. The individual ends of each column may, by means of these commutators, be connected separately or in groups to the apparatus of consumption, whether lamps or otherwise, which they are destined to feed. A bundle of iron wire fills the centre of the columns, and its magnetic action is regulated by the introduction of brass cylinders which may be seen in our engraving emerging from the upper platform, the object being to graduate easily the intensity of the secondary current, and consequently the intensity of the lamps. This movement of the brass cylinders is obtained by means of four circular handles on the side of the apparatus just below the upper platform.

A striking characteristic of this apparatus is that, although traversed by currents of the highest potential, every metallic part may be touched without producing the least shock. The management of the secondary generators is so simple that the company has been able, since the commencement of their working, to leave the apparatus, when once adjusted, in the hands of the unexperienced employés of the Metropolitan Railway. The generating machinery, which is located at the Edgware Road Station, consists of a steam engine of 25 horse-power running at 120 revolutions per minute, and supplied with steam from a Cornish boiler at 60 lb. pressure per square inch. The engine drives through counter shafting a Siemens W° alternating current dynamo machine running at 600 revolutions per minute, and excited by a small Siemens dynamo running at 1,000 revolutions per minute, the large dynamo giving 10,000 alternations per minute. The primary wire is led from the large dynamo to the secondary generator, after traversing which it is led out of the station and along the course of the line at the side of the tunnel to Notting Hill Gate Station, whence it returns to Aldgate, and thence is led back to Edgware Road, a total length of fifteen miles, including bends and turnings at stations. In the arc lamps Jablochkoff candles are used, while the incandescence lamps are those of Swan, the latter being fitted in the ordinary station lamps. This is a disadvantage, inasmuch as the frames of the lanterns, which are globular and in sections, cast shadows on the platforms. In other respects the light is very satisfactory, and although the stations do not present the brilliant appearance of those on other lines in which the arc light alone is used, and which is sometimes dazzling, there is a mellow light cast around ample for all practical purposes, and presenting a pleasant contrast to that of the gas at the stations on the Metropolitan Railway not yet electrically lighted.

It has been practically demonstrated that the loss occasioned by the transformation of energy into light by this system does not exceed 10 per cent. We need hardly point out how highly creditable this is to the Gaulard-Gibbs secondary generators. In view of the facts before us we cannot doubt that this system is destined to render important service in the economy of life. To give some idea of its possible development we may mention that it is intended to light by it the entire length of the Suez Canal by means of lamps placed on its banks and along its course through the lakes which it traverses, the whole being fed by a single cable about 200 miles in length, along which will circulate a current produced at one central station. In fact, in the Gaulard-Gibbs system we have the solution of a very important problem in electric lighting practically demonstrated.

Iron Age, Oct. 16, 84.

The Greatest Electrical Problem Unsolved.—Mr. Thomas A. Edison, having recently been asked what progress he was making toward obtaining electricity direct from the combustion of coal, instead of having to get it by first producing heat, then by heat steam-power, and finally electricity from the steam-power, said: "I have been working away at it for some months, and have got to the point where an apparently insurmountable obstacle affronts me. Working at the problem now seems to be very much like driving a ship straight for the face of a precipice, and when you come to grief picking yourself up and trying it again to-morrow. There is an opening in the barrier somewhere, and some lucky man will find it. I have got far enough to know that the thing is possible. I can get quite a current now directly from the combustion of fuel. Jablochkoff tried his hand at the same thing some years ago, and so did some Germans, but the results were laboratory curiosities only. I give myself five years to work at it, and shall think myself lucky if I succeed in that time. The unscientific world has no conception of what such a discovery would mean. It would put an end to boilers and steam engines; it would make power about one tenth as cheap as it is now; it would enable a steamship to cross the Atlantic at a nominal cost; it would enable every poor man to run his own carriage. It would revolutionize the industrial world."

around;* the planets whilst viewing their satellites, especially those of *Jupiter* in transit; portions of the moon, the details thus shown being sometimes very striking; sunspots or their nuclei, no diagonal being needed if the observer screws up the shutters very close before looking through the telescope; searching for comets or examining nebulæ and clusters.† As no clock is required for this instrument, and as all the shutters are at right angles to their neighbours, position angles can be very shrewdly calculated. To do this let the major star run along the edge of one or other shutter by turning the whole instrument on its axis, and bring a neighbouring shutter into the field. As the ordinary circular field is now reduced to an arc of 90°, the pos. angle can much easier be guessed.

Due thanks must be accorded to Mr. Mason, the optician, who resides in my neighbourhood, for his great ingenuity and patience in perfecting many manufacturing details in this contrivance, and to Mr. Wray, jun., who especially designed the deep positive eyepieces suitable to my requirements.

THE DISTRIBUTION OF ELECTRICITY.

THE first of a series of three lectures on this subject was delivered on Monday evening in the rooms of the Society of Arts, John-street, Adelphi, by Professor George Forbes, M.A., F.R.S.E. There was a large attendance, and great interest was manifested in the lecture, Mr. Forbes's remarks being several times cheered.

Professor Forbes said that when he was first asked to give this course of lectures on the "Distribution of Electricity" he thought it would be an interesting thing in a general and somewhat popular manner to give a description of the different schemes which had been proposed for lighting large installations and central station lighting, and to simply treat what had already been written in a general sort of manner. But as soon as he began to go into the questions at all, he felt it would be losing an opportunity for doing something which would be far more useful, and that was to talk on the subject from a more technical point of view than that which he had originally thought of, and to discuss somewhat fully these different systems and explain the defects of each and what were the relative merits of them, and really go into the question in a more thorough manner than anyone had found it worth his while up to the present time to attempt in these different problems. That, then, was the scheme he had before him in the course of those lectures. They all knew the different systems that had been proposed for lighting; they knew how the arc lights had been distributed in series, and how incandescent lamps had been put up, the multiple arc lamp on large stations, and more especially they were aware of what had been done in America. A great many eminent engineers had, doubtless, attacked the problem from the very beginning; but very few had written or published anything on the subject. It might be that, having expended a large amount of time in research, they were glad enough to remain possessors of the knowledge they had gained. In some cases only a special system had been marked out, and in very few cases had all the systems been relatively compared and pursued so as to bring out the most economical systems possible. Besides those two systems—the series system and the multiple arc system—they were aware that the latter was subdivided into a large number of different ways of distribution. They had all heard of the network system—a system with mains and lines of centres of distribution. So they had another one, which was called a multiple series system, which had been used to a certain extent very successfully, but which had some radical defects in it which had prevented its general adoption. At the same time it must be said that many distinguished engineers believed that in the future there might be a possibility of rendering this multiple series system efficacious, and of removing the difficulties which were in the way. The objection to the ordinary multiple system—where all the lamps were connected on to two massive mains, or a number of massive mains which were so connected as to make two massive mains; the objection to that system was the enormous cost of conductors. During the past few months there had been several committees started with a view of influencing the Board of Trade to take action in removing some of the restrictions in the Electric Lighting Act of 1882, which had proved such a hindrance to the progress of electric lighting. But besides that difficulty there was the fact that the Electric Lighting Act was simply unworkable, as every unprejudiced person must admit. There was another fact which had largely hindered electric lighting, and that was the enormous cost of mains. Not only that, but the multiple arc system introduced another serious expense. It became essential with such large mains to have rather a central station, with the engine in the centre of the district which was being supplied. In thickly populated districts, such as would be necessary in manufacturing the light on the multiple arc system, it was very difficult to get a site for the engine and dynamos, and it had been acknowledged by those who had undertaken to work the system in London to be one of the serious objections to the multiple arc system. It was of the utmost importance that engineers should devote their energies to the most economical system possible, whether that system be the multiple arc or the multiple series, or any of the modifications which had been proposed. At the present moment there were thousands of people in the city who were anxiously waiting to have the electric light supplied to their houses, but they were prevented from having it partly on account of the fact of the expense in the outlay, and partly by the gas monopolists and the assistance which the gas monopolists had received from the Electric Lighting Act of 1882. That would not much longer be maintained, he thought they could safely trust, and in that case they must be prepared as engineers with most economical means of laying down thick mains, so as to make electric lighting then a possibility in an economical and financial way. The question of the production of electricity was one on which he need say but little. At the present time electricity was produced by dynamo-machines, and that was by far the cheapest way, and there was no immediate prospect of any other system being introduced which was more economical. The question of primary batteries might be completely laid aside. There was no prospect that any primary battery would be rendered an economical means of producing electricity. It was true if it was possible to consume carbon in the form of coal or charcoal by oxidisation instead of consuming zinc they might have some economical battery which might compete with the dynamo. In 1880 he (Mr. Forbes) was engaged in making a number of experiments in that direction, but owing to an unfortunate circumstance they were discontinued; but many people had taken up the subject, and every now and then they heard prospects of something being done; but at the present moment they were very far from it, and before such a thing was done they would require something that would be entitled to rank as a real and original discovery—a discovery which did not come to them at the bidding, a discovery which was more often made in the laboratory of the patient investigator rather than in the workshop of the speculative inventor. Secondary batteries which were being supplied with their charge from dynamos might be looked upon as a means of supply rather than as a means of production of electricity. The same might be said of secondary generators, which had attracted considerable attention during the last year or two. He would now come to the problem before them—namely, the problem of the distribution and supply of electricity—but before attacking the problem directly he would take a general survey of the comparisons between electricity and gas in that respect. The production of gas was a far more complicated operation than the production of electricity. It was a somewhat complicated mechanical laboratory experiment produced on a large manufacturing industrial scale; but the distillation of the gas from the coal, and subsequent treatment by scrubbers, condensers, and lime purifiers previous to its introduction through a meter into the gas-holder and its supply to the service pipe, was a far more difficult operation than the similar problem in the case of electricity. When, however, they came to supply, the gas and electricity problems resembled each other a great deal. Gas must be supplied in pipes at a certain pressure, the size of the pipes must be regulated by the quantity of gas that was to pass through them, and the quantity of gas flowing through them must be so regulated that the pressure at the point of supply—namely, the burners—must not vary to any great extent. In all these points they had an analogue to gas in electricity. He should use the word "pressure" in speaking of electricity because it was used as a Parliamentary term, and it was a very convenient, and really, he believed, a scientific term—a pressure on any point to indicate the

* In using this instrument, the observer must bear in mind that it takes an appreciable time for the eye to recover the effect of the previous glare of the bright star; for that purpose it is well, I find, to keep the bright object some while behind a shutter before attempting to dismiss the field as barren. After a steady gaze a small star near α Sagittæ was observed Sept. 12, distinctly with the occulter, but *not visible* with my aperture (10in.) whilst employing ordinary means. We judged its P.A. 180. Mr. Burnham wrote to the ENGLISH MECHANIC some weeks after to say he had discovered it with the great instrument he uses. He judged P.A. 180·5 with his micrometer.

Iron. Aug. 1884.

AN ELECTRIC TORPEDO-BOAT.

ELECTRICITY has been called in to render the dreaded torpedo-boat still more formidable. An American, Professor Tuck, has built an electric submarine torpedo-boat, which looks at a little distance very much as if it had been constructed by laying a large row-boat upside down on top of another large row-boat, fastening them together and painting them both sea green. The shell of the new boat is of iron. The boat is 30 feet long, is ballasted with lead, so as to sink to the water's edge, and her displacement is 20 tons. In the centre of what may be called the deck is sunk a well hole. By a simple air lock arrangement, it affords a passage between the interior and exterior of the vessel, even when the vessel is wholly under water. It is also the captain's look-out station, and is capped with a dome of heavy glass, so that, if he chooses, he can exclude the water and stand in the pit with his head and shoulders above the top of the boat, or he can leave the glass off and stand there in a diving suit. Close to his hand is a signalling steering apparatus, which transmits his orders to the helmsman down below. The boat has three rudders, one an ordinary vertical rudder at the stern, and the other two horizontal blades on the port and starboard quarters. These last help to govern the boat's movements up and down. To sink her, water is pumped into her compartments; to raise her, air is pumped in, and the water is forced out. Compressed air is stored aboard in 6-inch pipes. There is also an apparatus for reoxygenating air that has already been breathed. Moreover, there is a simple arrangement by which the ends of two rubber tubes can be floated up to the surface of the water and opened to the supply of fresh air up there. An electric motor, driven by force from storage batteries, runs the propeller. The interior, which is arranged for a crew of four or five men, is lighted by incandescent lamps. An indicator shows the distance of the boat beneath the surface. The estimated speed of the boat under water is eight knots. The torpedoes are to be carried outside the vessel, one at the prow and one at the stern. They are to be held there in iron cylindrical sheaths by electro-magnets, which will release them when the current is cut off. They are ballasted with cork, and, after placing one of them, the torpedo-boat retires to a distance, unreeling as it goes two wires, by which, at a proper distance, the torpedo is fired. On a recent trial near the Delamater Ironworks, New York, a crew of three men went aboard her, and a test was made of the electric engine. It drove the boat several miles up and down the river at a speed of ten knots, when she answered her rudder well. She will soon be tried under water. The lead ballast proved insufficient to sink the boat below the water.

101

Iron Nov. 1884.

ELECTRICITY AND HEALTH.—Sir Frederick Abel, chairman of the council of the Society of Arts, delivered the opening address of the session on November 19. He dealt principally with electricity and the recent Health Exhibition, and commenced his address with a tribute to the memory of Sir William Siemens, who, the speaker remarked, "had he been present, would have rejoiced to bear testimony to the continued steady progress made during the past year in the application of the electric light." The recent Health Exhibition, the chairman continued, was an instance of this, for during the whole of that exhibition over 5,000 glow lamps and 334 arc lights, yielding a candle-power light of 375,000, were worked with a total expenditure of only 1,180 tons of coal; whilst other electric light installations, upon a much less extensive scale than at South Kensington, but still of considerable magnitude, had come into operation during the year. The application of the light in small quantities to private houses had been the subject of many experiments by well-known electricians, and considering that the glow lamp was only in the fifth year of its existence, there was every reason to be very hopeful of its future development in the direction of permanence and of the consequent cheapening of domestic applications of the electric light. After a glance at the development of electricity for military purposes, Professor Abel referred to the attempts to utilise the agent as a motor, alluding, en passant, to the Siemens electric railway at the Paris Exhibition, the line between the Vienna Exhibition and the Praterstern, the Portrush and Giant's Causeway Railway, the Brighton Electric Railway, and several experimental lines in America. The result of recent trials seemed to foreshadow a future for the employment of electricity as the motive power, not merely for small pleasure craft, but for small vessels in which silent progression is a desideratum sufficiently important to counterbalance the defect due to the limited period during which the motive power could be maintained; and as to the transmission of heavy weights by electricity, the public would shortly see a system in application at Millwall, devised by Professor Jenkin, for moving goods trucks by telpher lines suspended as telegraph wires now are. A considerable portion of the address was devoted to a review of the effects likely to result to the public from the Health Exhibition—"effects," said Professor Abel, "which cannot fail to prove fruitful of great benefit to the country." Sir Frederick admitted the mixed character of the collection, but, speaking generally, he expressed the opinion that it was replete with instruction and interest to the masses, and even to the most educated, whilst the conferences added much to that instructiveness. The sanitary and insanitary houses erected side by side in the grounds emphasised the increasing importance of the comparatively new profession of the sanitary engineer, and with regard to smoke abatement, a comparison of the collection at the Smoke Abatement Exhibition of two years ago and the Health Exhibition showed that there was no single instance in which makers had not made an effort to achieve an advance, either in the extent to which the escape of smoke and the wasteful consumption of fuel were avoided and ventilation secured in the warming of a room, or in simplicity of construction or arrangement of an already efficient stove. After a reference to the advantages, in this connection, of liquid fuel, Professor Abel passed to the consideration of the adulteration of food, and the benefits derived from the recent legislation, and in the course of some remarks on water supply he pointed out the disadvantages of the deep-well system, and expressed the opinion that our hope for a radical improvement in the water supply of London lay rather in the application of some simple, expeditious, cheap and effective mode of chemical treatment to supplies from sources now impervious to their filtration than in a complete change of the source of supply. The address concluded with an approving reference to the steps now being taken in the promotion of technical education.

NIAGARA FALLS CONSIDERED AS A SOURCE OF ELECTRICAL ENERGY.

The first suggestion of the possible employment of Niagara Falls as a source of electrical energy, and the distribution of this energy in the shape of light and power, is due to C. W. Siemens. It was a large suggestion; and it took root speedily in what may be termed 'cosmical minds.' The way, however, to its fulfilment, has not been made plain to business enterprise. The most noteworthy remarks upon the subject were made by Sir William Thomson in 1881, at the York meeting of the British association. His remarks and calculations were in substance as follows: With the idea of bringing the energy of Niagara Falls to Montreal, Boston, New York, and Philadelphia, a total electromotive force produced by the dynamo-machines at the falls was taken at 80,000 volts. This was between a good earth connection at the falls, and one end of a solid copper wire of half an inch in diameter, and three hundred statute miles in length. The resistance of the circuit was so arranged that there should be an electromotive force of 64,000 volts at the remote end, between the wire and the earth connection. The calculations showed that a current of 240 webers

not reached even the perfection which systems of electrical lighting have attained.

Railway News
april 23/85

When that eminent electrician, Sir Wil... Thomson, was in this country some few years since, he was much interested in the examination of Niagara Falls, not as most tourists are interested—from idle curiosity—but from a belief entertained by him that the day would come when the tremendous powers generated there and running to waste would be utilized in running the mills, if not the railroads, through the State of New York. He had no sooner made the suggestion, when the Illuminati, as is their wont when any one broaches an original idea, set up a howl of derision. They insisted that there was no reason to believe that anything of the kind would ever be accomplished; it was a purely chimerical idea, the product of a diseased mind. Then they went on to estimate the dimensions of a copper conductor required to transmit electrical energy one mile, increasing the diameter as they progressed until a few miles having been traversed, it was seen that the interest in the money expended for copper would alone amount to more than could be hoped for from the sale of the power transmitted from the great waterfall.

But while these purely ornamental scientists were trying to prove that the project was visionary, many practical electricians knowing Prof. Thomson's reputation for accuracy of statement, set to work to see what could be done in this direction. The progress these men or some of them have made is extraordinary, to say the least. Short lines of electrical railroads were among the first products of their exertions. Some of these were operated by electricity generated by coupling up a steam-engine and a dynamo at a central station and transmitting the energy along the line of the road while others, following Thomson's plan, were operated by electrical energy gathered on the banks of running streams. The best exponent of this system is found in the electric railway running between Portrush and Bush Mills in Ireland, and such success has been had in the operation of this road that it was recently extended eight miles.

The city of Rochester, New York, has for some time been lighted by electricity gathered on the banks of the Genesee River, the power being transmitted in a somewhat similar manner to that suggested by Prof. Thompson; and there are electric plants now in operation—a very large one in New York—which transmits not only light but also power to run shafting, and this over an ordinary copper conductor.

But what concerns us most and what led us to bring the subject before the readers of the RAILWAY NEWS, is the series of extraordinary experiments now being made in Paris by M. Marcel Deprez, in the transmission of electrical energy. Two years ago last March, Deprez, working in the railway shops of the *Chemin de Fer du Nord* in Paris, astonished the scientific world by transmitting twenty horse-power ten miles over an ordinary telegraph wire, and ten horse-power twenty miles, sustaining a loss in both instances, while in *transitu*, of a trifle more than fifty per cent. Considering that where power costs nothing at its place of production, a loss of even fifty per cent. is of little consequence. This was a wonderful achievement, and even the Illuminati who had come "to scoff remained to pray."

At the Exposition at Munich, Deprez repeated his experiment, and again at Grenoble about a year ago, where he collected power from a running stream ten miles from the city and operated the shafting of a mill with it. Quite recently, however, Deprez has made some even more valuable discoveries in the transmission of electrical energy; showing that short lines of railroad running from a common center, as in the case with a great city, can readily be run by electricity brought to this common center from a running stream miles away, or from the mouth of a coal-pit where fuel is cheap.

There is a promise in the future in this direction that we wot not of.

London – Iron Trade
May 2/85

In the current number of the *Fortnightly Review* there appears an interesting article on "Recent Progress in Electricity," by Mr. Julius Maier. The article is instructive not only to persons directly interested in electricity, but to all those who have interest or stake in any modern industry. It may fairly be said that there is scarcely any trade on which the increasing application of electricity to practical purposes has no influence. Electric lighting is looked upon as an entirely new discovery, and it is not generally known that the electric light was employed for the purposes of illumination as early as the middle of the eighteenth century. Up to our own days, however, the electric light, though interesting as a scientific experiment in the lecture room, was not employed for practical purposes, owing to the vast amount of elements in the galvanic battery needed for its production. The new and practical era of electric lighting was heralded by the discovery of the principle of the dynamo-machine by Faraday, in 1830. The first really successful dynamo-machine was constructed by Gramme, in 1870, and since then progress towards perfection has been rapid, though perfection has by no means been obtained as yet. The serious objection to the introduction of electric lighting into general use is its cost of production. Even at the present day, it cannot compete with gas in cheapness. With the present system of converting heat into work by means of the steam engine, loss is entailed not only in the conversion of heat into work, but also in the transmission of the work thus obtained to the dynamo machine. Another principle is that of the thermo-electric battery. The defect in these batteries was the low standard of electro-motive force obtained. These are the only two systems at present discovered, though Mr. Julius Maier points out that there is no reason why some investigator may not be enabled to apply solar heat to the production of electricity. The other important element in electric lighting is the lamp. Of these, two species are in vogue, the arc and the incandescent lamps. Of these, the arc seems to have a future before it for lighting public buildings and thoroughfares, while the incandescent lamp seems destined, when perfected, to perform the task of domestic lighting. One of the most important applications of electric lighting has been to collieries, and it is to be hoped that ere long an Act of Parliament will compel owners to adopt the electric light in their mines. The importance of such a step will be realised on reflecting that in 1880 four hundred and ninety persons were killed by mine explosions in Great Britain. Mr. Maier further draws attention to the application of electricity to the transmission of sound in the now familiar telephone, and of energy as foreshadowed in the experiments made by Mr. Deprez, in 1882 and 1883. It was discovered by Mr. Deprez, that energy might be transmitted to a long distance with a loss of from 50 to 60 per cent. of original motive power. Further applications of electricity are found in the electric boiler safety apparatus of Mr. Richard Schwarzkopff, of Berlin, an invention whereby a boiler may be secured against danger arising from over-heating, excessive steam pressure, and want of water. Dr. Boulet has successfully applied electricity to medical purposes in his pulsometer, cardiaphone and myophones, the two latter for articulation of the heart and muscles, respectively. Though the public interest is at present centred more in the electric light, that is by no means the only new application of electricity which our days have seen, and it may be safely predicted that in no long time we shall be dependent on electricity for well-nigh all the ordinary appliances of every-day life.

Electricity and Boiler Explosions.

Two terrific boiler explosions yesterday—one in the Tremont Hotel, Galveston, and the other in a sawmill a few miles from Wilkesbarre—caused the loss of five lives and serious injury to several persons, of whom some may not recover. In neither the hotel nor the mill could any satisfactory substitute for steam be found, perhaps, but the explosions direct attention to the advantage of introducing electricity in place of steam to all the buildings of cities where small engines are now used. Electricity is cheaper than steam where less than ten-horse power is required, and its safety is a much more important consideration. The transmission of power by wires under the streets will permit the removal of thousands of small steam boilers from buildings in this city, and the substitution of a dynamo for every engine of less than ten-horse power would promote both convenience and safety. It is asserted by electricians that the substitution would be advantageous even where more power than that of a ten-horse engine is used, and it is not improbable that a great change will be effected in this direction within a few years. Where large engines are used their management can always be entrusted to an expert, and statutory provision should be made to require this to be done; but the fact that electricity is cheaper than steam where small engines are employed will be sufficient to effect the desired change in establishments of this class as soon as the electricians supply the desired facilities. For heating purposes steam will always be extensively employed, probably; but experience has demonstrated the advantage of using steam from pipes in the street, rather than from a boiler in the basement.

N. Y. Tribune
May 2, 1885

...electric invention is by no means at an end. On the contrary it is more active than ever. It is being directed, however, rather to the application of electricity than to the discovery of new forces or powers. Electric lighting is in itself possible of world-wide application, but methods of the use of electricity in light may be wholly revolutionized at any time. George W. Stockley, of Cleveland, secretary of the Brush Electric Light Company, said the other day: "There is nothing especially new in the electric light world. It is settling down into a staple business. It has never been a speculative business with us. Those companies which pushed into speculative channels have nearly all burst up. The storage battery is not being pushed into the general market, and will not be until further changes are made in it. The trouble is that it requires more skill and intelligence to operate it than a sewing machine or a furnace, and the ordinary run of people will not give it the necessary care. The Pennsylvania Railroad Company is using the storage battery to light cars between New-York and Philadelphia, and has no trouble in its operation. The effort is being made to make a battery that any one can manage.

Menlo Park Scrapbook, Cat. 1051

No. 35. "Electric Lamp"

This scrapbook contains clippings about electric lamps. It covers the years 1879-1886, but most of the material is for 1879. The spine is labeled "Vacuum Pump--Tube--Radiometer--Elect. Lamp." There are 144 numbered pages.

Blank pages not filmed: 100-144.

New Electric Mining Lamps.

A late number of the *Colliery Guardian* gives a long account of Andre's electric mining lamp, claiming its great desirability in mining operations, sub-aqueous works, and in factories where explosive agents are dealt with.

The light is enclosed in a strong glass cylinder, open only at its lower end, which rests in an air-tight seating upon the base of the lamp. By this means the atmosphere is securely excluded, and explosions of fire-damp certainly prevented. The cylinder is protected by rods on the outside; the lamp is constructed to be suspended from these rods, and the latter are utilized to pass the electric current in to the carbons. Being thus complete in itself, the lamp, when not in action, may be easily carried about from place to place, and suspended at any point required. The lamp consists essentially of four small carbon rods or pencils, enclosed in a series of vertical tubes. A light weight in each of these tubes above the carbon rod forces the latter down as its lower end is consumed. This weight is not heavy enough to break the point of the carbon, even when the point has become very fine, so that no unpleasant flickering occurs as the carbon descends, and no waste is occasioned. The arrangement of the carbon rods and the weights in tubes obviates the necessity for the strings required in other electric lamps working on the same principle of incandescence. The lower ends of the carbons rests upon discs of copper, which constitute the negative poles. The metal being incombustible, only one pole, the positive, is burned away. When the current is impeded by the accumulation of silicious dust from impurities in the carbon the disc turns slightly, and the point of the carbon sweeps the impediment away; and should the carbon rod fail to descend, by sticking in the tube, the disc rises and breaks it away from its point of contact.

The glass cylinder being air-tight, the combustion of the carbon is retarded through lack of oxygen, and finally ceases altogether. Practically, however, a slow waste occurs, due, perhaps, to oxygen occluded in the carbon, or possibly by the disintegrating action of the electric current. When the first carbon rod has been consumed, or if from any other cause it becomes extinguished from an interruption of the circuit, the current passes automatically to the second of the series. This rod is then slowly consumed, like the latter portion of the first. From the second, the current passes in like manner automatically to the third of the series, and from this again to the fourth. The total duration of the four carbons, which are each 9 inches in length, varies from 500 to 600 hours, according to the strength of current used.

There is no risk of the lamp being extinguished, because, in case of an interruption, the automatic action of the commutator switches the current from one carbon to the next in the series. The intensity of the light is about 75 candles. The light is regarded of great importance, in consequence of its superiority and the non-vitiating and non-heating of the atmosphere of the mine. It also works well under water, in works where caissons are used.

Edison's Discovery.

Mining Sc Press Sept 20 1879

Mr. Edison has not yet revealed any additions to his knowledge of the use of electricity for illumination, but his paper on the treatment of platinum wire, read at the session of the American Association for the Advancement of Science at Saratoga, is almost as interesting as a discussion of the electric light would have been. Platinum, made incandescent by a hydrogen flame or by an electric current, wastes away or burns until nothing is left. This prevents its use for illuminating purposes. He found this to be caused, not by volatilization, as generally understood, but by detrition, the currents of gas rubbing off fine particles. He prevented this by coating the wire with oxide of magnesium.

By further experiments Mr. Edison supplemented Dr. John W. Draper's discovery that platinum wire in a Bunsen flame becomes disintegrated. He states in his paper the fact that all metals have air spaces in them, and that these interstices are the origin of the cracks which become visible through a microscope after incandescence, and to the naked eye in platinum if a wire is stretched between clamp posts. These being the conditions, Mr. Edison put his platinum under the receiver of a powerful air-pump, and by alternately subjecting it to the action of a vacuum and sending an electric current through it to aid the expulsion of air by warmth, he produced a wire in which "no cracks were visible" by the microscope. "The wire had become as white as silver, and had a polish which could not be given it by any other means. The wire had a less diameter than before treatment, and it was exceedingly difficult to melt in the oxyhydrogen flame. As compared with untreated platinum, it was found that it was as hard as the steel wire used in pianos, and that it could not be annealed at any temperature."

Mr. Edison adds: "My experiments with many metals treated by this process have proved to my satisfaction, and I have no hesitation in stating that what is known as annealing metals to make them soft and pliable is nothing more than the cracking of the metal. In every case where a hard drawn wire has been annealed a powerful microscope revealed myriads of cracks in the metal."

Further experiments showed that a very much higher illuminating power could be obtained at a much less expenditure of force than in the original platinum. He has made, in fact, a new kind of platinum, and other metals, by the same process, are transformed in the same manner.

unclear p. 2

ANDRE'S ELECTRIC MINING LAMP.—A short time ago, the inventor of this important aid to the safe working of coal mines, explained its construction and working in a very perspicuous and exhaustive manner to an influential meeting at the offices of the British Electric Light Company, Parliament Street. Mr. Andre showed the perfect adaptability of his lamp to the lighting of fiery collieries and mines generally. The atmosphere being securely excluded from the light, the risk of explosion, with its fearfully disastrous effects, is entirely avoided, and this end is attained advantageously and economically, for the light emitted is of great power, and the cost far less than that of safety lamps or candles. The Duke of Sutherland, Professor Keats, and Mr. Easton, C.E., who were present, highly commended the design of the lamp as thoroughly practical in all its details. His Grace, on taking leave of Mr. Andre, expressed his satisfaction at the success attained, and remarked that the lamp had a great future before it. The lamp exhibited will burn 600 hours in a mine without being touched, four carbons being thrown into light automatically one after another. There are now good grounds for hoping that the terrible calamities of fire damp explosions may be averted. It may be added that the lamp is applicable to all mining operations, and particularly to sub-aqueous engineering works.

Engineering Sept 26 1879

MR. EDISON'S LAST DISCOVERY.

Whenever the prognostications of sanguine newspapers concerning Mr. Edison's electric light were falsified, it was said that Mr. Edison was not responsible for that which he had not himself said; at last he has spoken himself, and that of very wonderful discoveries indeed in a paper "On the Phenomena of Heating Metal in Vacuo by the Electric Current," read before the American Association at Saratoga Springs. The substance of his discovery is that by exhausting air or something else from platinum while at a high heat its durability is enormously augmented, as well as its power of giving out light. If a short length of platinum wire, one-thousandth of an inch in diameter, be held in the flame of a Bunsen burner, at some part it will fuse, and a piece of the wire will be bent at an angle by the action of the globule of melted platinum; in some cases there are several globules formed simultaneously, and the wire assumes a zigzag shape. With a wire four-thousandths of an inch in diameter this effect does not take place, as the temperature cannot be raised to equal that of the smaller wire, owing to the increased radiating surface and mass. "After heating, if the wire be examined under a microscope, that part of the surface which has been incandescent will be found covered with innumerable cracks. If the wire be placed between clamping posts, and heated to incandescence for twenty minutes, by the passage of an electric current, the cracks will be so enlarged as to be seen with the naked eye; the wire under the microscope presents a shrunken appearance, and is full of deep cracks." If the current is continued for several hours these effects will so increase that the wire will fall to pieces. Mr. Edison states that the cause of the shrinking and cracking of the wire is due entirely to the expansion of the air in the mechanical and physical pores of the platinum and the contraction upon the escape of the air, and that by eliminating the air with the aid of syringe pumps he has succeeded in producing "a metal in a state hitherto unknown and which is absolutely stable at a temperature where nearly all substances melt or are consumed—a metal which, although originally soft and pliable, becomes as homogeneous as glass and as rigid as steel. When wound in the form of a spiral it is as springy and elastic when at the most dazzling incandescence as when cold, and which cannot be annealed by any process now commonly known." This is not all, Mr. Edison goes on to state that by the increased capacity of platinum to withstand high temperature, he is able to employ small radiating surfaces, and thus reduce the energy required per candle light. "I can now obtain eight separate jets, each giving out an absolutely steady light, and equal to sixteen standard candles, or a total of 128 candles, by the expenditure of 30,000 foot-pounds of energy, or less than one-horse power. The most astounding statement of all is, however, contained in the following passage:—"As a matter of curiosity, I have made spirals of other metals, and excluded the air from them in the manner stated. Common iron wire may be made to give a light greater than platinum not treated; the iron becomes as hard as steel, and just as elastic. Nickel is far more refractory than iron. Steel wire used in pianos becomes decarbonised, but remains hard and assumes the colour of silver. Aluminium melts only at a white heat." This means that the fusing points of the metals named is enormously increased by heating them slowly to very high temperatures in vacuo. Thus, for example, aluminium in its ordinary condition melts at a full red heat. Assertions so remarkable and so publicly made will not be suffered to pass unquestioned. It is extremely desirable that the inquiry should be taken up in this country, and pushed to its limits.

Arloing

La Correspondance Scientifique 30 Sept 1879

La Bougie Jablochkoff

La Société Générale d'Electricité (procédé Jablochkoff) vient d'obtenir une récompense bien méritée, après plus d'une année de luttes et d'expériences heureuses. Le concours international de l'Exposition des Pays-Bas, qui s'est tenu à Arnheim, lui a décerné une médaille d'or et une mention honorable pour les procédés Jablochkoff.

Cet éclatant succès donne une actualité toute particulière à une notice très intéressante et très instructive que la Société Générale d'Electricité vient de publier, notice qui répond si bien aux attaques et aux objections qui sont faites relativement à l'emploi de la bougie Jablochkoff. Mettre sous les yeux de nos lecteurs les quelques lignes de cette notice, c'est répondre victorieusement à ces attaques et à ces objections :

Le prix d'installation d'un bec de gaz étant de 100 francs, et celui d'un foyer électrique de 1,609 francs, on voit que l'installation d'un foyer électrique, dans le cas où elle revient le plus cher par suite de l'emploi d'un moteur spécial, ne coûte pas plus que celle de 16 becs de gaz. Donc, toutes les fois qu'un foyer électrique remplacera 16 becs de gaz, l'installation ne coûtera pas plus cher, bien que l'intensité lumineuse soit *supérieure* à celle des 16 becs.

Quant au prix de consommation, voici les conclusions de la notice :

D'après les résultats indiqués ci-dessus, on voit que 126 becs de gaz sont remplacés avec avantage par 6 foyers électriques brûlant à nu et donnant une lumière supérieure et une économie de 34 pour cent.

Il en résulte qu'en réalité, au point de vue de la dépense, un foyer électrique ne coûte pas plus que 8, 3 becs de gaz, en donnant une lumière supérieure.

Les globes opalins dont les foyers sont ordinairement environnés absorbant environ 1/3 de la lumière produite, on doit admettre que toutes les fois que 10 à 11 becs de gaz sont compris dans la zone d'éclairement d'un foyer électrique, on pourra les remplacer par un foyer électrique donnant une puissance éclairante supérieure sans augmentation de dépense.

En rapprochant ce résultat de celui qui a été trouvé plus haut, on voit que lorsque 16 becs de gaz seront remplacés par un foyer électrique, on aura égalité de prix d'installation et économie de consommation, avec une quantité de lumière plusieurs fois supérieure.

L'économie qui résulte de l'emploi de la lumière des bougies électriques substituées au gaz pour l'éclairage des espaces où le nombre des becs est déjà considérable n'est donc pas discutable.

D'ailleurs, outre cet avantage capital, cet éclairage présente les qualités suivantes :

1° Il conserve les couleurs et permet de différencier les teintes les plus voisines, ce qui serait impossible à la lumière du gaz. Dans toutes les industries où l'on doit se rendre compte de la qualité des

as fast as he could, and reached a solid standing-ground, but not before perceiving that the guide, who walked behind him, had sunk up to the middle in the sand, and indeed soon disappeared. All the slope sank with increasing swiftness, swelling out at the bottom and opening out to give forth a stream of mud of at least ten metres in height, which shot like a wild torrent across the plateau, and precipitated itself towards the Val de Bove. Immediately all the moving sand, to more than thirty metres in height, was diluted and drawn along, as were also the stones and blocks it contained, and which rolled over each other pell-mell. Fortunately they succeeded in extricating the guide, covered with mud, torn and bruised.

Seeking the origin of these eruptions of mud, M. de Saussure observes first that they take place in the neighbourhood of the central cone of Etna, and that they all escape from the foot of the cone and the very inclined slopes which support it. They proceed then exclusively from the water stored in the beds of ashes. These causes seem to account for this mass of water. 1. The hot vapours. The cone seems almost exclusively composed of ashes and movable stones, and during the eruption an enormous mass of vapour must have traversed it. There are, moreover, numerous fumeroles in the upper part. These vapours have been condensed, all the more readily that they have encrusted the mantle of snow which envelops the summit of the mountain. 2. The melting of this snow, determined less by the fall of ashes on the surface than by the heat which radiates from the interior and the vapours which traverse the porous mass of the cone. 3. The abundant vapours falling from the cloud of vapours projected by the crater. The two first causes are the most important; the last has most especially given rise to surface streams, the traces of which are apparent. The water gradually collecting in excess in the lower parts of the cone, ends by forming these enormous deposits, which, at a given moment, yielding to their weight, cause an eruption to the outside, turning over and diluting the beds of ashes which oppose its exit.

In a communication to us M. de Saussure gives an analysis of the little mud-heaps which have projected through the snow. They are composed of a grey powder formed of pozzolana (spongy amorphous silicates), white, grey, and black (augite), mixed with (b) amorphous sulphur (yellow and orange coloured); (c) calcium sulphate (hydrated) in numerous well-defined small crystals; (d) sodium and potassium sulphate; (e) calcium and potassium chloride; (f) perchloride of iron and oxychloride of iron; (g) indication of copper salts.

The crystals are all of alabaster, and so wet that they can only have been formed after the eruption of the mud in drying. There is no crystallised silica nor feldspar. The sulphur in the mud is curious to observe. It must have condensed out of the eruptive vapours which formed the water to make the mud by mixing with old ashes under the snow, and by their expansion driven small quantities of that mud through the snow. This mud, when heated, evaporates sulphur, sulphurous and sulphuric acid, some perchloride of iron, and some hydrochloric acid.

THE ACTION OF HEAT IN VACUO ON METALS[1]

Nature Oct 21 1879

IN the course of my experiments on electric lighting I have developed some striking phenomena arising from the heating of metals by flames and by the electric current, especially wires of platinum, and platinum alloyed with iridium. These experiments are in progress.

The first fact observed was that platinum lost weight when heated in a flame of hydrogen, that the metal coloured the flame green, and that these two results continued until the whole of the platinum in contact with the flame had disappeared. A platinum wire four-thousandths of an inch in diameter, and weighing 306 mgrms., was bunched together and suspended in a hydrogen flame. It lost weight at the rate of a fraction less than 1 mgrm. per hour as long as it was suspended in the flame. When a platinum wire is stretched between two clamping posts, and arranged to pass through a hydrogen flame, it is coloured a light green; but when the temperature of the wire is raised above that of the flame, by passing a current through it, the flame is coloured a deep green. To ascertain the diminution in the weight of a platinum wire when heated by the electric current, I placed between two clamping posts a wire five-thousandths of an inch in diameter, and weighing 266 mgrms. This wire, after it was brought to incandescence for twenty minutes by the current, lost 1 mgrm. The same wire was then raised to incandescence; for twenty minutes it gave a loss of 3 mgrms. Afterwards it was kept incandescent for one hour and ten minutes, at which time it weighed 258 mgrms.—a total loss of 8 mgrms. Another wire, weighing 343 mgrms., was kept moderately incandescent for nine consecutive hours, after which it weighed 301 mgrms., showing a total loss of 42 mgrms. A platinum wire twenty-thousandths of an inch in diameter was wound in the form of a spiral one-eighth of an inch in diameter and one-half an inch in length. The two ends of the spiral were secured to clamping posts, and the whole apparatus was covered with a glass shade 2½ inches in diameter and 3 inches high. Upon bringing the spiral to incandescence for twenty minutes that part of the globe in line with the sides of the spiral became slightly darkened; in five hours the deposit became so thick that the incandescent spiral could not be seen through the deposit. This film, which was most perfect, consisted of platinum, and I have no doubt but that large plates of glass might be coated economically by placing them on each side of a large sheet of platinum, kept incandescent by the electric current. This loss in weight, together with the deposit upon the glass, presented a very serious obstacle to the use of metallic wires for giving light by incandescence, but this was easily surmounted after the cause was ascertained. I coated the wire forming the spiral with the oxide of magnesium, by dusting upon it finely powdered acetate of magnesium: while incandescent the salt was decomposed by the heat, and there remained a strongly adherent coating of the oxide. This spiral so coated was covered with a glass shade, and brought to incandescence for several minutes; but instead of a deposit of platinum upon the glass, there was a deposit of the oxide of magnesia. From this and other experiments I became convinced that this effect was due to the washing action of the air upon the spiral; that the loss of weight in and the coloration of the hydrogen flame were also due to the wearing away of the surface of the platina to the attrition produced by the impact of the stream of gases upon the highly incandescent surface, and not to volatilisation, as commonly understood; and I venture to say, although I have not tried the experiment, that metallic sodium cannot be volatilised in high vacua by the heat derived from incandescent platinum; any effect that may be produced will be due to the washing action of the residual air. After the experiment last described I placed a spiral of platinum in the receiver of a common air-pump, and arranged it in such a manner that the current could pass through it, while the receiver was exhausted. At a pressure of 2 millimetres the spiral was kept at incandescence for two hours before the deposit was sufficient to become visible. In another experiment, at a higher exhaustion, it required five hours before a deposit became visible. In a sealed glass bulb, exhausted by a Sprengel pump to a point where a quarter of an inch spark from an induction-coil would not pass between points 1 millimetre apart, was placed a spiral, the connecting wires passing through the glass. This spiral has been kept at the most dazzling incandescence for hours without the slightest deposit becoming visible.

I will now describe other and far more important phenomena observed in my experiments. If a short length of platinum wire one-thousandth of an inch in diameter be held in the flame of a Bunsen burner, at some part it will fuse, and a piece of the wire will be bent at an angle by the action of the globule of melted platinum; in some cases there are several globules formed simultaneously, and the wire assumes a zigzag shape. With a wire four-thousandths of an inch in diameter this effect does not take place, as the temperature cannot be raised to equal that of the smaller wire, owing to the increased radiating surface and mass. After heating if the wire be examined under a microscope, that part of the surface which has been incandescent will be found covered with innumerable cracks. If the wire be placed between clamping posts, and heated to incandescence for twenty minutes, by the passage of an electric current, the cracks will be so enlarged as to be seen with the naked eye; the wire, under the microscope, presents a shrunken appearance, and is full of deep cracks. If the current is continued for several hours these effects will so increase that the wire will fall to pieces. This disintegration has been noticed in platina long subjected to the action of a flame by Prof. John W. Draper. The failure of the process of lighting invented by the French chemist Tessie du Motay, who raised sheets of platinum to incandescence by

[1] A Paper read by Mr. T. A. Edison before the American Association for the Advancement of Science; Saratoga Meeting.

NEW FORM OF REYNIER'S ELECTRIC LAMP.

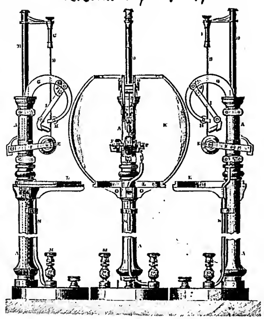
In 1878 Mr. E. Reynier observed the advantages presented by the effects of incandescence for the simple production and division of the electric light, and conceived the idea of uniting these effects with those of the voltaic arc. He therefore arranged the carbons, according to the Lodyguine system, so that it would burn at the point and furnish a small center of combustion at the point of contact. A small voltaic arc was thus produced.

Sc. Am. Sept 27 1879

In this lamp a slender rod of carbon is placed above a fixed and massive contact, either of carbon or metal, and is held in a vertical position by a heavy carbon holder. The carbon holder, by means of its weight, gradually pushes the carbon rod downward to replace the parts burned away. Cinders will collect at the point of contact if the ordinary carbons are used, but these cinders are thrown off by the rotation of the carbon disk. With this apparatus Mr. Reynier illuminated five lamps with a current from thirty Bunsen elements, and maintained the light in one of the lamps for more than a quarter of an hour with a secondary battery of three Planté elements.

Fig. 1 is a side view of the lamp without globe. Fig. 2 is a front elevation with section of globe and support. Fig. 3 is an elevation of the other side. A is the hollow supporting column with base; B is a slender carbon rod fitted to the socket, C, and retained by a screw. The vertical rod, D, supports the carbon rod, B, and slides in the column, A, on friction rollers. The carbon disk or cylinder, E, upon which the end of the carbon, B, rests, is supported in a forked arm, F. The carbon slides between the two cheeks of the curved guide, G. There is a small wheel, H, at the end of the guide, G, against which the carbon rod, B, rests, and an inclined lever, I, is pressed by the spring, J, against the carbon rod, and acts as a brake. A glass globe, K, covers the whole.

Mr. Reynier has made several models of his lamps. The last has a Carré carbon about 0·08 of an inch in diameter, held by a heavy carbon holder, which slides in a hollow column, and is provided with four friction rollers. The carbon rod rests on a carbon cylinder pivoted to a vertical arm of the column. A guide piece, provided with a brake, holds the carbon rod, and through this guide the current passes into the carbon rod, and from thence to the carbon cylinder, and returns to the battery. The point of contact is not directly over the center of the cylinder, but a little to one side, so that the cinders cannot accumulate.



REYNIER'S ELECTRIC LAMP.

¾ bar, 2½ inches at a cut. It has an open back, and will admit a plate 14 inches wide, and of course any length. The opening in the bed is 7x9 inches; stroke of slide 1½ inch; adjustment of slide 1½ inch. It weighs about 1,200 lbs., and

523. Electric Light, J. T. and W. R. Bousfield.—Dated 10th February, 1879. 6d.

Engineer Oct 3 1879

A rotating armature is used made in the form of a drum, and composed of longitudinal sections secured in place by end plates, which are mounted on the armature spindle. These sections consist of segmental armatures, the core of which is preferably /—/ shaped in cross section, the flanges being set radially, and the induction coils laid longitudinally round the core. Or the sectional armatures may be made by coiling insulated wires on flat bars lengthwise in such manner that when placed together the periphery of the drum would present to the exciting magnets an unbroken surface of copper coils; the cores would, as in the former case, be connected magnetically. The Second part relates to holding and feeding, say, the positive carbon in an electric lamp. The carbon is held in a grooved holder, through which, when no current is passing, it slides freely until it touches the negative electrode. When the current passes the carbon is gripped tightly in its holder.

NOUVELLE LAMPE ÉLECTRIQUE

A INCANDESCENCE (SYSTÈME REYNIER).

On se souvient que le principe des lampes Reynier consiste à maintenir incandescente une mince baguette de carbone, par le passage d'un courant électrique qui la traverse sur une partie limitée de sa longueur, entre un *contact en bout* sur lequel elle bute, et un *contact latéral* dans lequel elle glisse en progressant.

Nous avons montré aux lecteurs de *la Nature*[1] les diverses dispositions successivement imaginées par l'inventeur pour mettre en pratique ce principe original.

La Nature 27 Sept 1879

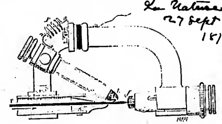

Fig. 1.

Continuant à perfectionner son système, M. Reynier vient de réaliser un nouveau *bec* électrique plus simple encore que ses précédents dispositifs, et qui va sans doute faire entrer les lampes à incandescence dans l'éclairage courant. Ce nouveau bec est représenté figure 1.

Le charbon C, poussé dans le sens de la flèche par un mécanisme quelconque, bute sur le *contact en bout* R; le *contact latéral* L, monté à l'extrémité d'un levier, s'appuie sur le charbon par le tirage d'un ressort *r* et limite entre i et *j* l'incandescence de la baguette.

Le contact en bout R est monté dans un porte-contact fixé à baïonnette dans la douille intérieure du bec. Pour introduire le charbon dans la lampe, on retire ce porte-contact, qui laisse libre l'orifice du tube; on pousse le charbon dans ce tube, puis on remet en place le contact en bout; et l'appareil est prêt à fonctionner.

L'incandescence, avons-nous dit, se manifeste entre *i* et *j* sur une longueur qu'on peut faire varier entre 4 et 8 millimètres. La lumière obtenue est de cinq à vingt becs Carcel par foyer, selon l'intensité du courant électrique et la longueur d'incandescence qu'on s'est donnée. Avec une pile de huit éléments Bunsen plats (modèle Ruhmkorff), on produit une lumière équivalente à douze becs Carcel environ. Quand on fonctionne avec des machines magnéto-électriques, on peut produire, par cheval-vapeur, de trois à cinq foyers valant chacun huit à quatorze becs, ce qui fait un rendement de trente à quarante becs Carcel par force de cheval.

Étant donné le bec, il était aisé de l'adapter à des lampes de formes diverses. M. Reynier a fait des appareils marchant de haut en bas par l'action d'un contrepoids ou d'une poussée hydrostatique, un modèle à barillet fonctionnant dans toutes les positions et un appareil suspendu, le plus simple de tous : c'est celui que nous représentons figure 2.

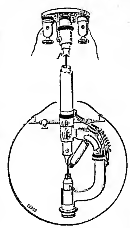

Fig. 2.

Ici, la progression du charbon est obtenue par la descente du cylindre *p*, qui pèse directement sur la tête du charbon.

SUR L'EMPLOI

DES PILES HYDRO-ÉLECTRIQUES

ET DES LAMPES REYNIER

POUR L'ÉCLAIRAGE DOMESTIQUE.

Nos nouvelles lampes électriques à incandescence, devenues simples, commodes et sûres, peuvent fournir de trois à cinq foyers par cheval-vapeur. Ces appareils trouveront donc un débouché important dans les usines et les grands établissements pourvus d'un moteur; car tout en fournissant un fractionnement plus grand qu'aucun autre système, les nouveaux foyers conservent un rendement photométrique assez satisfaisant (30 à 40 becs Carcel par cheval); de sorte qu'ils réalisent sur le gaz une économie sensible, en offrant des qualités de blancheur, de fixité, de salubrité, etc., qui en font un éclairage de luxe.

En dehors de ces applications, nos lampes à incandescence pourraient prendre place dans les in-

CHRONIQUE DES PROGRÈS DE LA LUMIÈRE ÉLECTRIQUE

Electricity
20 Aug 1879

Les expériences sur la lumière électrique ont obtenu un tel succès à Londres que le Bureau métropolitain des travaux publics s'est décidé à conserver les bougies Jablochkoff pendant une nouvelle période de six mois et à en augmenter le nombre d'une façon notable.

En effet, aux soixante bougies qui éclairent les quais de la Tamise, depuis le pont de Westminster jusqu'au pont de Blackfriar, viendront s'ajouter vingt autres qui illumineront le pont de Waterloo et la grande avenue Northumberland, allant du quai de la Tamise à la place Trafalgar.

Les amis du gaz sont consternés, car ils voient arriver flamboyante la grande nuit où les bougies Jablochkoff accapareront cette grande place, assiégeront le Parlement et, s'avançant par Regent Street, marcheront à la conquête du parc qui est le rendez-vous de la fashion universelle.

Pavillon des Halles Centrales illuminé par la lumière Jablochkoff

Cette éclatante victoire justifie nos assertions cent fois répétées et explique les attaques dont elles peuvent avoir été l'objet. Elle nous permet de ne point tenir compte des démentis qui pourront nous être adressés, pas plus que de ceux qui l'ont déjà été.

Elle prouve combien nous étions heureusement inspirés en avertissant, au commencement de ces expériences, les actionnaires du gaz du danger de les laisser commencer, car l'électricité est du nombre de ces ennemis qu'il faut étouffer dans le berceau, écraser dans l'œuf, étrangler au moment où ils se présentent.

Nous sera-t-il permis d'ajouter que le grand succès définitif obtenu à Londres est dû à l'innovation que nous avons réclamée depuis longtemps : la suppression des opales et leur remplacement par des globes à peu près transparents.

Toutefois, nous négligerions une occasion presque unique de mettre en évidence un grand fait général, si nous omettions de faire comprendre la nature des hésitations de la Compagnie générale d'Electricité.

Il fallait, en effet, faire l'éducation de l'œil du public, qui se serait plaint d'être inondé de clarté, si on lui avait montré dans les premiers temps la lumière Jablochkoff sans être atténuée.

Il serait arrivé quelque chose d'analogue à la combustion spontanée dont périt Sémélé, lorsque Jupiter eut la faiblesse de se rendre à ses prières et de se

AGENTS FOR "ENGINEERING."

MANCHESTER: John Heywood, 143, Deansgate.
GLASGOW: William Love.
EDINBURGH: John Menzies and Co., 12, Hanover-street.
FRANCE: Lacroix, 54, Rue des Saints Pères.
BELGIUM: P. Bailly, 12, Rue de l'Archevêché, Brussels. Kirkland and Cope, Ostend.
UNITED STATES: Lenox Smith, 48 Pine-street, New York.
VIENNA: Lehmann and Wentzel, Kärntnerstrasse. Gerold and Co.
LEIPZIG: Alphons Dürr. F. A. Brockhaus.
BERLIN: Messrs. A. Asher and Co., 5, Unter den Linden.
CALCUTTA: G. C. Hay and Co.

Advertisements cannot be received for insertion in the current week later than 5 P.M. on Thursday. The charge for advertisements is three shillings for the first four lines or under, and eightpence for each additional line. The line averages eight words. Payment must accompany all orders for single advertisements, otherwise their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper and on the inside pages may be obtained on application.

The price of ENGINEERING to annual subscribers in the United Kingdom receiving copies by post is 1l. 9s. 2d. per annum, this including two double numbers. If credit be taken, the charge is 2s. 6d. extra, the subscriptions being payable in advance.

FOREIGN SUBSCRIPTIONS.

The rate for subscriptions to ENGINEERING from abroad are:
1l. 16s. 8d. For Australia (via Southampton), Austria, Belgium, Brazil, Canada, China (via Southampton), Denmark, Egypt (via Brindisi), France, Germany, Greece, India (via Southampton), Italy, Netherlands, Natal, New Zealand (via Southampton), Norway, Portugal, Russia, Spain, Sweden, Switzerland, and United States of America.
2l. 4s. For Australia (via Brindisi), China (via Brindisi), India (via Brindisi), and New Zealand (via Brindisi).

All accounts are payable to the publisher, Mr. CHARLES GILBART, 37, Bedford-street. Cheques should be crossed "Union Bank, Charing Cross Branch." Post Office Orders to be made payable at 467, Strand, London, W.C.

Office for Publication and Advertisements, No. 37, Bedford-street, Strand, W.C.

ENGINEERING is registered for transmission abroad.

READING CASES.—Reading cases for containing twenty-six Numbers of ENGINEERING may be had of the publisher or of any newsagent. Price 3s. each.

NOTICE TO AMERICAN SUBSCRIBERS.

We beg to announce that we have appointed Mr. Lenox Smith, 48, Pine-street, New York, the sole agent for ENGINEERING in the United States, and all subscriptions for the United States will in future be payable to him. Mr. Lenox Smith is also prepared to receive advertisements for ENGINEERING, and will afford full information as to terms, &c., on application. The annual subscription for ENGINEERING delivered post free in the United States is 13 dols. U.S. currency payable in advance.

ENGINEERING.

FRIDAY, OCTOBER 10, 1879.

THE PHYSICAL ALTERATION OF METALS.

AT the meeting of the American Association for the Advancement of Science which has recently been held at Saratoga an announcement was made by Mr. Thomas Alva Edison of a discovery made by him, which, from its interesting nature and the probable value of its application, is quite equal to, if it does not surpass, the many discoveries and inventions that he has already given to the world. The public, more especially that portion of it interested in the development of the electric light, have for some months been expecting great things from Mr. Edison, as it has been a matter perfectly well known that he has throughout the whole of this year been devoting himself to the solution of the great problem of the day—the application of electricity to economical illumination—and Mr. Edison and his accomplished work are too well known for much doubt to exist as to important results accruing from a research to which he was with all his exceptional resources directing so much attention.

When it was announced a few months ago that Mr. Edison was experimenting with an alloy of iridium and platinum, and with each metal separately, for the production of the light-giving portion of an incandescence electric lamp, it was with considerable truth surmised that the former metal was too difficult to obtain in the first instance, and too refractory to work in the next, and the latter substance, besides being difficult to get, was too liable to destruction by fusion to render very promising the practical and commercial success on any extended scale of the employment of those metals in the then known distribution of them, and with their then understood physical character. Mr. Edison, so far from being blind to these difficulties, which would have been stumbling-blocks to less energetic investigators, set himself to search for fresh and more plentiful sources of supply of these precious metals by which they would become less precious, and at the same time to prosecute a research into the phenomena taking place when these metals were rendered incandescent under different physical conditions. If report from the other side of the Atlantic speak the truth, the search which Mr. Edison set on foot for new sources of supply has met with very considerable success, and of the successful results of his own experiments on the physical aspect of the question no further proof is needed than his very remarkable and interesting paper which was read before the American Association, and which must give to the Saratoga meeting a special historical feature.

Observing that a platinum wire heated to incandescence in a hydrogen flame gave to the latter a greenish tinge, at the same time losing its own weight, Mr. Edison made some careful quantitative measurements to ascertain the nature and extent of the loss sustained by the platinum. He took a bundle of platinum wire four-thousandths of an inch in diameter, and suspended it in a hydrogen flame. Before the experiment the platinum weighed 306 milligrammes (about 4¾ grains), and during its period of incandescence it lost weight at the rate of about [illegible] milligramme (.015 grain) per hour. Mr. Edison also noticed that a platinum wire within a hydrogen flame produced upon that flame different effects when deriving its temperature of incandescence solely from the flame itself, and when superheated from an external source; thus a platinum wire glowing with incandescence within a hydrogen flame by which it was heated, imparted to it a pale green colour, but when a current of electricity was passed through it so as to heat it above the temperature of the flame, the latter assumed a much deeper tone of green, and it would seem from this that the depth of colour is in some way connected with the amount of platinum being thrown off per unit of time, in other words, with the rate at which it is losing its weight under the conditions in which it is placed. In one experiment a platinum wire weighing 343 milligrammes (nearly 5.3 grains) was maintained for [illegible] hours in an incandescent state, at the end of which time it was found to have lost no less than 42 milligrammes in weight (.65 grains); and when a spiral ⅛ in. in diameter and ½ in. in length composed of fine platinum wire was enclosed within a small glass shade and maintained in a state of incandescence for twenty minutes by the passage through it of an electric current, it was found that the inner surface of the glass shade became slightly coated with metallic platinum, and that after five hours of such treatment the deposit became so thick as to be perfectly opaque to the light emitted by the incandescent spiral, and Mr. Edison states his conviction that by a process founded on this phenomenon, large plates of glass might be coated with pure metallic platinum as reflecting surfaces with great economy by placing between them a sheet of platinum rendered incandescent by the passage through it of an electric current. Mr. Edison's explanation of the physical cause of this phenomenon is very interesting, and we cannot do better than present it to our readers in Mr. Edison's own words. "From this and other experiments," he says, "I became convinced that this effect was due to the washing action of the air upon the spiral; that the loss of weight in and the coloration of the hydrogen flame were also due to the wearing away of the surface of the platinum by the attrition produced by the impact of the stream of gases upon the highly incandescent surface, and not to volatilisation as commonly understood." And the author in his paper goes on to describe a series of experiments in support of this theory, in which no such wearing away or diminution of weight was produced when the spiral was enclosed in a bulb which was exhausted by means of a Sprengel pump to such a degree that the discharge spark from an induction coil would not strike across a distance of one millimetre; in this experiment the spiral was maintained at the most dazzling incandescence for several hours without the slightest deposit being formed upon the surface of the glass envelope.

It is very interesting in turning over the pages of the history of the progress of science during the last half century to observe the different aspects with which different philosophers at different periods regarded certain facts of science, certain substances, and certain phenomena connected with them, how in their different views they seemed to arrive at different results; but as the observations of other investigators approaching the subject from different directions came to be recorded, and the great oneness and harmony of nature asserted itself in the human mind, things the most apparently opposite united their forces to support the truth, proving only that the conditions were the only agents in opposition, that the different positions assigned to the same phenomena by different observers were the result of a sort of mental parallax, and that Nature could not in these or anything else be divided against herself. Want of space will not permit us in this place to enter into the researches which bear more or less upon Mr. Edison's recent discoveries made by previous investigators, but the names of Döbereiner, of St. Claire Deville, of Troost, of Faraday, and of Graham, will recall a multitude of researches bearing on the occlusion and dispersion of hydrogen gas by certain metallic substances, more especially platinum, palladium, iridium, and certain other of the tetrad metals, under various physical conditions. It was found by Professor Graham that platinum, whether in the form of wire or of foil, is capable of absorbing when at a low red heat nearly four times its volume of hydrogen (measured cold), and that palladium foil condenses more than six hundred times its volume of hydrogen at a temperature below that of boiling water, and that in the spongy state platinum absorbs 1½ times its volume of hydrogen, and palladium nearly one hundred times.* Thus hydrogen so occluded at comparatively low temperatures, and at ordinary pressures, is driven out again, when the metal which has absorbed it is subjected to the action of heat and to a diminution of pressure, and Mr. Crookes in some of his beautiful experiments has taken advantage of these phenomena for varying the internal pressure within his exhausted vessels without having to use the Sprengel exhauster. The facts recorded by Mr. Edison of the diminution of weight in metallic wires when rendered incandescent at ordinary pressures are enhanced in interest by comparing them with the researches of the pioneers in the science of the subject to whom we have alluded; and the modification of the phenomena when atmospheric pressure is removed, and when the same experiments are conducted in high vacua taken in conjunction with Mr. Edison's explanation of it, adds very great interest to the recent researches of Mr. Crookes upon radiant matter, for while the last-named investigator has shown how, by the impact of gaseous molecules upon the vanes of a mill, mechanical motion may be imparted to them, and by the concentration of the streams of such molecules upon a small area the most intense heat may be produced, Mr. Edison has shown that these molecules, infinitesimally minute as they are, are so thoroughly material in nature that their friction on the surface of the heated platinum is sufficient to rub away its substance, transporting its particles to another place in a manner analogous to the action of the very interesting sand-blast process of Mr. Tilghman, for the cutting and engraving of stone, glass, and other hard substances.

From these experiments, which form the subject of the first part of his paper, Mr. Edison was led to undertake a minute examination of the structure of the substance of wires of platinum and other metals before and after being subjected to incandescence. In the course of this examination he found that the effect of incandescence upon wires experimented upon was to produce all over their surface innumerable cracks, and when the incandescence was maintained for twenty minutes these fissures became so enlarged as to be visible to the naked eye, and when still further continued for several hours the cracks united and the wire fell to pieces, and Mr. Edison points out that a somewhat similar phenomenon had been noticed by Professor Draper in platinum plates which had for a long time been subjected to the action of flame. A number of experiments made by Mr. Edison have led him to the conclusion that this cracking up of the surface of the metal is due entirely to the occluded gases imprisoned within its mechanical and physical pores becoming expanded and driven out under the action of heat, these gases first separating the molecules of the metal, then tearing their way through it to the surface, and escaping by the cracks and fissures so produced, a sort of microscopical volcanic action going on within the metal, producing miniature "earthquakes" and fissures on its surface out of which the heated gases are emitted. By heating spirals of platinum wire gradually by means of a transmitted electric current of periodical increasing strength, and within a chamber exhausted to a pressure of two millimetres, the gaseous bodies contained within their substance were gently withdrawn; and, by allowing the metal in the interval, between each increase of

* Philosophical Transactions, 1866.

temperature to cool down, a series of expirations of air from its surface took place alternating with a closing up and welding again together of the minute fissures through which the gentle heating *in vacuo* had enabled the gases to escape. The pores of the metal thus became converted into an infinite number of what might be called molecular valves opening outwards whenever subjected to the gaseous pressure from within caused by the action of heat, but closing and welding up again with increased density at each alternate cooling. By continuing this very simple operation Mr. Edison has been able so completely to change the physical character of the metals subjected to the process, that he may almost be said to have produced new substances altogether, for he has done what is almost the same thing, he has produced metals in a state such as has never been known before, increasing their hardness and density to an extraordinary degree and raising their points of fusion so high that they are perfectly unaffected in temperatures at which most substances would be melted or consumed and very many would be volatilised. Most persons are aware that when a spiral of platinum wire is heated to a bright incandescence it softens and loses its elastic or rigid character, but it has been reserved for Mr. Edison to discover that when the same spiral is subjected to this alternate gradual heating and cooling in an exhausted chamber it becomes as homogeneous as glass and as rigid as steel, and its melting point is so enormously raised that a fine spiral so treated is, at a temperature at which it is glowing with an incandescence of dazzling brilliancy, as springy and elastic as when cold, and cannot be annealed by any known process.

The great value of Mr. Edison's discovery, as far as the electric light is concerned, lies in the power which it places in the hands of the metallurgist of raising the fusion point of platinum and of other metals beyond the reach of destruction by the transmission of the electric current, and if we understand Mr. Edison's experiments correctly, it is almost impossible to overrate the value of their results to the development of the science of electric illumination and more immediately to that branch of the subject which deals with lighting by incandescence. The hitherto insurmountable difficulty in the way of illumination by incandescence has been the low fusion point of those metals which can be obtained commercially, and when obtained which can be worked, and our readers will remember that a few months ago* Mr. Edison included in a patent a large number of most ingenious devices for protecting a platinum spiral from destruction by its own incandescence, and there have been devices suggested and patents applied for, almost without number, for bringing about the same result. The fact, however, remained that platinum in its normal condition is when sufficiently incandescent to be useful for illumination purposes in a highly delicate state of unstable equilibrium, a delicately poised balance, so to speak, between extinction from cooling on the one hand, and destruction from fusion on the other, and none of the very pretty protectors, so far as we have been able to learn, have been found to work satisfactorily in practice. Recourse was next had to using a substance possessing a still higher fusion point, and this was found in the metal iridium, but this is both difficult to get, and, therefore, very costly, and still more difficult to work into wire. Mr. Edison has, however, met with some considerable success, as have the Anglo-American Electric Light Company, in the employment of an alloy of platinum with iridium, an alloy which combines, to a certain degree, the refractibility of the one metal with the malleability of the other; and, as such, gave somewhat promising results, but for the reason stated above, it could hardly have come into very general application. Here then comes in the great value of Mr. Edison's new discovery, for he can, speaking *incandescently* (and by that we do not mean talking the language of a red-hot republican, but speaking from the point of view of the requirements of incandescence), make a spiral in platinum and convert it when so made into iridium, or more correctly speaking, he can make his light-giving portion of platinum, which is easily drawn and manipulated, and when so made he can confer upon it a fusion point higher than the purest iridium, and without any fear of fusing it or of affecting its rigidity.

Mr. Edison has actually produced by his process spirals of platinum wire which could be raised by the passage of the electric current to such a high temperature without fusion, that their incandescence gave out a light of 25 standard candles, while the same coils not treated by the process gave a maximum light of but four candles at their point of destruction by fusion. One spiral which had been submitted to the vacuum heating process more gradually, and for a longer period, produced a light of thirty candles, and the surface of all the wires so treated was in all cases free from roughnesses or cracks of any kind, presenting a brilliantly polished surface; they were as hard as the steel used for pianoforte wires, and by no process could they be annealed.

When we state that by preparing spirals in a Sprengel vacuum very slowly, and allowing a great many alternate heatings and coolings to take place, Mr. Edison has produced a light-giving body, whose total radiating surface is only $\frac{1}{32}$ in., which emits a light of eight standard candles, and that without the treatment the same spiral could hardly have produced one candle's light without fusion, and that he has thereby been enabled to produce eight lights, each of 16-candle power, or 128 candles in all, by the expenditure of less than one horse power, we have, we think, said enough to show the great importance of Mr. Edison's discovery to the single application of electric lighting, and it would be unreasonable to suppose that it has not still wider and more important applications. We shall on an early occasion refer again to this interesting subject, and to its probable bearing upon other branches of the science of illumination by electricity.

STEEL RAILS.

We publish elsewhere in the present issue (*vide* page 292) a letter from Mr. C. P. Sandberg, on a subject which is of particular interest just now, when there is some prospect of a revival in our steel trade, and when every item of saving in the cost of manufacture of steel rails has a special importance. The object of Mr. Sandberg's letter is to direct attention to the injury which steel rails now not unfrequently receive in the process of straightening cold, and to suggest a remedy in the shape of an arrangement of rolls by which rails are straightened while hot as they leave the saw, this plan having already been brought into use in America with very satisfactory results. It must be understood that Mr. Sandberg's remarks refer particularly to flange rails—rails of the double-headed or bull-headed sections being much less liable to injury from the ordinary process of straightening.

There can be no doubt that as Mr. Sandberg points out, fractures of steel rails sometimes occur which can only be explained by the supposition that the metal has received local injury, and the suggestion that such injuries are largely due to mal-treatment during the cold straightening process is a very plausible one. There can also be no doubt that it is the occurrence of such fractures as have just been referred to that has had an important influence in leading engineers to increase the severity of their tests, until it has been rendered impossible for these tests to be satisfied without using a steel which is softer than is desirable as far as the power of resisting wear and tear is concerned. If, therefore, a cause of local injuries can be removed, a direct benefit will be obtained not only by the rail maker, but also by the rail user, who will be enabled to frame his specification so as to obtain harder rails than he feels justified in using under present conditions.

Altogether the subject is, as we have said, one of much importance, and we are glad that Mr. Sandberg has drawn attention to it. No doubt there are many of our readers who have had special experience in the matter referred to, and we shall be glad to make public any facts which they may be able to lay before us. The time has, also, we think, arrived when the subject of the best standard tests for rails of different weights and sections might be discussed with advantage. The tests now prescribed by different engineers, differ greatly in severity, and it would be of much interest to know how far these different tests are justified by the results obtained. On the one hand an insufficiently severe test may lead to the passing of rails of defective quality, while on the other, an unduly severe test tends to the supply of rails which are too soft to give the best results as regards wear, and, moreover, unnecessarily, increases the first cost. Steel rails have now been sufficiently long in use for a great number of facts to have been collected respecting the endurance and trustworthiness of rails made under systems of testing, and those who are in possession of such facts would do great good by making them public. It is indeed only by the interchange of such experience that real progress can be secured, and for this reason we shall have much pleasure in throwing our columns open to the publication of such data as we have referred to.

LOCOMOTIVE CRANK AXLES.

On the Correct Shape and Dimensions of the Crank Arms in Locomotive Crank Axles.

By J. A. Hinckel.

That crank axles are made to be broken is a dictum which will hold good, as long as the inside cylinder engine with its undoubted advantages finds an advocate. Yet if cheapness of material and economy of labour in the process of manufacture have made the renewal of crank axles a matter of comparatively little moment, this is no reason why we should not endeavour to ascertain whether some neglected point in the proportions of such axles does not, in a great measure, account for their liability to fracture, and if we detect such a fault to remedy it accordingly.

It is well known that these fractures occur most frequently in the neck of the crank, and sometimes partly through the neck and partly through the arm; both cases are illustrated by the accompanying sketches, Figs. 1 and 2 (see opposite page) and the author has it on the authority of one of the oldest locomotive engineers of the United Kingdom, that a partial fracture takes place first, after which the axle continues to do duty very often for a considerable time without any apparent increase of fracture before being finally disabled. A curious phenomenon like this demands a rational explanation, and this explanation can be none other but the following, namely, that the axle has established for itself, by this partial fracture, the conditions of flexibility which it requires to possess, in order to live and to do its work.

The author believes that the main point on which are based his recent researches on slide bars (see Engineering, page 95 *ante*) will enable him to show that without a considerable amount of flexibility in the crank arms the axle is hopelessly doomed to break.

It has been shown in the paper on slide bars just referred to, that the shock to the bars due to the lateral displacement of the wheels corresponds to a pressure equal at least to double the weight of the wheels and axle with all the parts that move sideways along with them, that shock being communicated to the bars by means of the connecting rod.

It follows, by Newton's principle, that the axle meets with an equal resistance to its lateral displacement, and as the mass $\frac{w}{g}$ (w being the weight of the wheels and axle with all the parts moving along with them laterally) has acquired its lateral momentum prior to the shock $2\,w$ taking place, and as that momentum can only be destroyed by lateral displacement, it follows that unless the crank arms can yield by their own structural flexibility, some molecular disruption must take place to permit of this lateral displacement.

If, for instance, in the accompanying Figs. 3 and 5, we assume the retarding force $2\,w$ to act in the direction of the arrow in the centre line of the neck of the crank, the part of the moving mass lying to the left of it will, by virtue of its acquired momentum, move in the opposite direction, and if $n\,w$ be the weight of that portion, v its initial velocity of lateral displacement, and v_1 that velocity after the shock, we shall have

$$2\,w\,s = \frac{1}{2}\,\frac{n\,w}{g}\,(v^2 - v_1^2) \quad . \quad . \quad (1)$$

s being the space through which the retarding force $2\,w$ has been acting, or in other words, the space through which the portion $n\,w$ has been able to move relatively to the portion lying to the right of the crank, either by the structural flexibility of the arms, or by the accidental flexibility due to partial fracture.

From equation (1) above we make

$$s = \frac{n}{4\,g}\,(v^2 - v_1^2) \quad . \quad . \quad . \quad (2)$$

and as $(v^2 - v_1^2)$ is, to our certain knowledge, a quantity having a real, though unknown value, we know also that s has a real though unknown value, or more precisely, we know that the crank-fork must have opened by a certain amount, either through the structural flexibility of the arms, or through partial molecular disruption in or near the neck of the crank, and to avoid this latter contingency the arms ought to be made as flexible as possible.

Passing now to the consideration of the strains on the body of a crank axle, it is to be observed

THE KRUPP ELECTRIC LAMP.

Herr von Krupp, of Essen, has recently patented an invention for "Improvements in Electric Light Apparatus." The main object of the invention is to regulate automatically the position of the carbons of an electric lamp "in a simpler manner than heretofore, without abandoning the generally acknowledged conditions on which the precision of motion of the single parts depends." The invention includes the application of a brake appliance for the automatic regulation of the distance between the two carbon points. A fan or fly revolves in quicksilver, or other liquid, for the purpose of regulating the motion of the carbon holder, this part of the apparatus being designed as a substitute for clockwork. A magnetic coil with iron casing and iron bottom is employed in connection with the motion of the brake appliance.

Fig. 1, in the engraving, which we take from *Engineering*, is a side elevation, and Fig. 2 a front elevation of the lamp, in which A is the holder for the upper positive carbon, and B the holder for the lower negative carbon. The upper holder, A, is suspended from the disk or pulley, C, by means of a jointed chain or wire, the lower holder, B, being similarly attached to a disk or pulley, D, the latter disk being just half the size of the former. The chains or wires are so passed round the pulleys that when the holder, A, descends a certain distance by its weight, the other holder, B, ascends to half the distance. Accordingly the electric arc formed between the carbon points occupies a fixed position. As the weight of the upper holder, A, must not be too small, because its motion would then be easily influenced by dust and dirt, it is necessary to have an appliance for retarding and regulating its course or travel. For this purpose a fly or fan, E, is applied, which revolves in mercury or other liquid. On the spindle of this fly there is a pinion, F, which gears with a tooth wheel, G, on the spindle, X, of the chain pulleys, C and D. In order that the fly, E, by the insertion of a fresh carbon should not have to revolve backward, the toothed wheel, G, is fitted with a pawl wheel, H.

The setting and regulating of the proper distance between the carbon points is effected in the following manner: On the same spindle, X, as the pulleys, C and D, and tooth wheel, G, there is a disk, I, as shown in the separate view, Fig. 3. Fig. 4 is a separate view of a brake of a peculiar form acting on this disk, I. The brake consists of two parts, K and M, which are jointed together at L. The lower part, M, can turn on the spindle, X, and has a hole, M¹, in which is inserted a small peg, N, Figs. 1 and 2. The peg, N, has much play in the hole, and the backward motion of the brake is limited thereby. O is a brake block on the upper part, K, of the brake; P is the keeper for an electro-magnetic coil, Q. This keeper is by a brass rod suspended from the other end of the part, K.

When the lamp is in action the keeper, P, is drawn into the coil, Q, whereby the brake block, O is pressed against the disk, I, turning the latter in its further movement downward, that is, so far as the set screw, R, Fig. 1, will allow. Thus, the upper carbon point will be raised, and the lower carbon point lowered, and the electric arc then makes its appearance. The carbon points now gradually consume away, the current becomes weaker, and its effect on the electro-magnet, Q, is lessened. The brake, K, supported by the spring, S—the action of which can be suitably regulated in proportion to the strength of the current by means of the lever, U, and set screw, V—and by the weight of the carbon holder, moves slowly back. The brake disk, I, is thereby enabled to turn forward, and the carbon points can approach each other. When this movement has proceeded as far as the brake disk, I, moved back before, then the lower part of the brake comes to bear against the peg, N. By the further weakening of the current, the brake will now turn in its joint at L, the brake block, O, releases the disk, I, and the carbon points move toward each other, whereby the current is strengthened and the brake is again applied to the disk, I, either simply to hold it when the carbon points are in their right position, or to pull it back when the carbon points are too close together. When inserting new carbons, the brake is fixed by the set screw, W, and the work is arrested thereby. The electro-magnetic coil, Q, rests on the bed plate, T, of the lamp, and is surrounded by an iron casing, whereby its power of attraction for the keeper is increased.

The fixed position of the arc provides for keeping the light in the center of a concave reflector. Where this is not required, the lamp may be simplified by leaving out the moving parts for the lower carbon holder, making it fixed instead of movable. The lamp thus devised has been employed by Herr von Krupp in portions of his great factory at Essen, in Germany, and the results have been so satisfactory that the light is being extended to other parts of the establishment.

KRUPP'S ELECTRIC LAMP.

14

THE TEMPERATURE OF THE CARBON POINTS IN THE ELECTRIC LAMP.

Engineering Oct 31 1879

Early in the development of the electric light a difference was observed in the appearance of the two carbon terminals. The positive was blunt and hollowed out in the centre; the negative was conical, pointed, and covered with the particles disintegrated from the positive. This, together with the difference of brilliancy noticed when the image of the carbons was projected on a screen, led to the same conclusion, viz., a difference of temperature between the incandescent points.

In 1844, Foucault and Fizeau wrote a paper upon this subject in which they described the general phenomenon, but gave no data from which the heat condition of the two poles could be inferred. It was not until 1862 that any careful measurements were made. In that year, the late M. Becquerel made a series of experiments on the temperature of the positive carbon. The current was supplied by a battery of 80 middle-size Bunsen cells, and the temperature was taken at the moment the light flashed forth. M. Becquerel concluded that this temperature was not constant, but that it varied between the limits of 2070 deg. C. and 2100 deg. C. Unfortunately an assumption was made by the French physicist which has since been disproved, and hence the above figures have not been generally accepted.

It may be remarked that this determination is beset with considerable practical difficulties. The radiating surface must be small, a mere slice of the glowing carbons, and yet it must be measured with great accuracy. M. Rosetti, an Italian physicist, who has been following up the work begun by the late Professor Henry and Father Secchi on the temperature of the various parts of the solar disc, has recently applied his method to this electric problem. He has found that the temperature of the incandescent carbons, at the moment of ignition, is not the same throughout and is effected by a variety of circumstances, *e.g.*, the thickness of the terminals, the number of cells in the battery, the way in which they are coupled together, and the time they have been charged.

Thus in one series of experiments, the temperature of the positive terminal was found to be 2950 deg. C. By using a thinner terminal, it rose to 3065 deg. C.; and by changing this for a third of still smaller dimension, it reached 3136 deg. C.

The effect of the number of cells in the battery on the temperature is shown in the following Table:

Number of Cells.	Temperature.
80	2784 deg. C.
70	2536 "
60	2334 "
50	2190 "

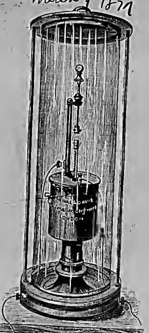
Foucault showed photometrically that the light produced by a battery of 80 Bunsen cells lost one-third of its intensity in less than three hours. Hence M. Rosetti was obliged to make a large number of determinations including all the varying conditions above mentioned before he could arrive at any very definite conclusion. In every case, however, he found the temperature of the positive pole higher than that of the negative; and, summing up his experiments, he concludes that the temperature of the positive carbon point cannot be less than 3200 deg. C. whilst that of the negative is at least 2500 deg. C.

15

SUBMARINE ILLUMINATION.

The conditions to be observed in the construction of lamps for giving light under water are many and difficult. Such lamps, like those used in an explosive atmosphere, must of course be isolated from the surrounding medium. There is also the additional requisite that, for a given degree of illumination, a greater intensity of light is needed to pierce the denser fluid. It is evident that there are strong objections against the use of ordinary gas or oil lamps for submarine illumination. They require an extra pump for their air supply, as much hose as the diver, and also as many men to attend to them; so that, for a necessarily feeble illuminating power, not only is the first cost considerable, but the working expenses are heavy and continuous. The cumbrous attachments are also a drawback.

March 9 1877



ELECTRIC SUBMARINE LAMP.

OXY-CARBON SUBMARINE LAMP.

Two modes of overcoming these difficulties are shown in the accompanying engravings. In one apparatus, that of Messrs. Heinke & Davis, the problem is solved by the aid of electricity. This light will burn below water without any air whatever; and it is stated by *Iron* that when the parts of the lamp are screwed together no further attention is required. The upper illustration on this page shows the construction of this apparatus. The strength of the electric light allows the substitution of a glass cylinder for the usual bull's eye lens and reflector, and thus a uniformly diffused light is produced. The cylinder is fitted to a segmental ring, and can be removed by turning it to the extent of one eighth of the circumference. The lamp is made of polished brass, the top and bottom portions being connected together by strong brass rods. A plate of lead at the bottom gives the necessary weight to balance displacement, and also causes the lamp to sink and remain steady when placed on the bottom. The lamp may be burnt continuously or intermittently, as required by the nature of the work; the carbons are usually arranged so as to last about four hours without renewal. Electricity is supplied by a battery of from twenty to forty Bunsen's elements, according to the intensity of light required. The bottom of the lamp is fitted with stuffing boxes, by means of which the wires connecting the lamp with the battery may be connected or disconnected at will, without the necessity of severing the wires. The total weight of this lamp, which gives a light equal to 20,000 normal candles, is about 60 lbs. It may be used independently of surface connection.

Another plan is that of Messrs. Barnett & Foster, who use the system represented in the lower engraving. The light consists simply of the flame of a spirit lamp, urged by a jet of pure oxygen, compressed in a wrought iron bottle to about thirty atmospheres; and when one remembers what brilliant coruscations are produced by incandescent charcoal plunged in oxygen, it will readily be conceived that such a light is exceedingly powerful. This arrangement possesses the advantage of being entirely self-contained, dispensing with all pipes and connections from the surface. Exit valves are provided for the gaseous products of combustion, and the oxygen receiver is fitted with a rope, by which a diver can sling it on his back and walk about with it easily. The ordinary supply of materials will furnish a brilliant light for four hours.

... Edison und das elektrische Licht.

(Für den "Techniker" von Ernst Gundlach.)

Der Techniker March 1879

Das Edison'sche Princip des Zweigstromes.

Unter den Erfindern auf dem Gebiete der Elektricität nimmt Thomas A. Edison entschieden einen hervorragenden Rang ein. Wir brauchen nur auf seine zahlreichen Erfindungen für Verbesserungen der telegraphischen Duplex- und Quadruplex-Gegensprech-Apparate, auf seine elektrische Feder, auf sein elektro-chemisches (lautsprechendes) Telephon und auf seine elektrischen Messinstrumente, wie das Mikrophon und den Mikrotasimeter, und schliesslich auf seinen zwar praktisch werthlosen, aber bedeutend ausposaunten Phonographen und andere Erfindungen hinzuweisen. Seitdem nun der berühmte Erfinder von Menlo Park in dieser Weise die Aufmerksamkeit der ganzen civilisirten Welt auf sich lenkte, konnte es nicht fehlen, dass auch auf verwandtem Gebiete, wie dem des elektrischen Lichtes, resp. der praktischen Einführung desselben — die gleichzeitig und überall mit grösstem Eifer angestrebt wurde und noch wird — Edison für den Auserwählten angesehen wurde, der das grosse Problem endlich zur glücklichen Lösung bringen werde. Kein Wunder, dass die ersten Nachrichten über wirklich von Edison auch auf diesem Gebiete gemachte Studien und Experimente und deren angeblich wahrhaft grossartige Resultate sofort überall unbedingten Glauben fanden. Edison hatte — so hiess es — die Erfindung gemacht, das elektrische Licht auf den Strassen, in Theatern, Privatwohnungen, kurz, überall einzuführen, wo überhaupt künstliche Beleuchtung gebraucht wird. Die Gas-Compagnien bekamen eine Gänsehaut und die Oelquellen verloren die Lust, weiter zu springen. Illustrirte Journale brachten bereits Abbildungen von mit Edison'schem Lichte beleuchteten Privaträumen und alle Welt identificirte bereits das elektrische Licht mit Edison und liess alle übrigen Erfinder auf diesem Gebiete fast unbeachtet.

Obgleich nun mittlerweile nach und nach die Details der Edison'schen Projecte und Erfindungen durch Veröffentlichung seiner Patente der allgemeinen Beurtheilung zugänglich gemacht worden sind, so haben sich der Autoritätsglaube und die sanguinischen Hoffnungen dennoch bis heute in so hohem Grade aufrecht erhalten, dass eine ernste kritische Prüfung der bis jetzt bekannten Edison'schen Erfindungen im Gebiete der elektrischen Beleuchtung wohl nicht mehr als angemessen erscheinen dürfte.

Die Basis des Edison'schen Projectes ist die sogenannte "Theilung" des elektrischen Stromes, zu dem Zwecke, um eine *grosse* Anzahl Lichtherde von entsprechend *mässiger* Leuchtkraft von einer gemeinschaftlichen (centralen) Elektricitätsquelle aus zu speisen und vermittelst verbindender Leitungsdrähte auf *grosse* Räume (ganze Städte) zu vertheilen.

Alle *vor* Edison gemachten Versuche dieser Art stimmen ausnahmslos darin überein, dass die betreffenden Lichtapparate oder Lampen sämmtlich in *eine* und *dieselbe* Stromleitung *hintereinander* eingeschaltet wurden und dass also der an einer Centralstelle erzeugte, starke elektrische Strom z. B. von einer Strassenlaterne zur anderen, durch den, alle Laternen verbindenden Leitungsdraht gehen musste. Diese Versuche hatten den grossen Uebelstand, dass eine etwaige Unterbrechung der ganzen Leitung an irgend einer Stelle derselben, sei es ein Fehler an der Lampe selbst, oder das durch irgend einen Zufall etwa herbeigeführte Zerreissen des Drahtes, *das sofortige Erlöschen sämmtlicher Lichtherde* zur Folge hatte. Ebenso theilte sich jede Unregelmässigkeit in dem Funktioniren einer Lampe allen anderen mit, so dass dieselben gewissermassen einen fortwährenden Kampf gegen einander führten.

Edison's Project beseitigte nun diesen Uebelstand durch Anwendung des — an und für sich durchaus nicht neuen — Princips des sogenannten *Zweigstromes*, indem er z. B. einen *starken* Haupt-Leitungsdraht durch die Strassen zieht und an diesem überall da, wo eine Lampe durch einen Strom für das Licht gespeist werden soll, einen *dünneren* Nebendraht abzweigt, der nach der betreffenden Lampe geleitet und dann wieder nach dem Hauptdrahte, in geringer Entfernung von der ersten Verbindungsstelle, zurückgeführt wird. Ein solcher Nebendraht nimmt von dem Hauptdraht einen geringen Theil seines elektrischen Stromes für sich in Anspruch. Die Stärke dieser Ableitung, resp. die dadurch verursachte Schwächung des Hauptstromes, richtet sich sowohl nach dem Verhältniss der *Dicke* des Nebendrahtes zu der des Hauptdrahtes, wie auch nach der *Länge* des Nebendrahtes zu der *Länge* des zwischen den beiden Verbindungspunkten liegenden Hauptdrahtes, d. h. je dünner und länger der Nebendraht im Vergleich zum Hauptdraht ist, desto schwächer der in den Nebendraht abgeleitete Strom, resp. desto geringer der Verlust des Hauptstromes.

Es leuchtet hieraus ein, dass man durch entsprechende Drahtdicke und Länge dem für die Lampen bestimmten Strom eine beliebige Stärke geben, und ferner, dass eine etwaige Unterbrechung des Zusammenhanges des Nebendrahtes nur die eine einzige Lampe erlöschen machen, auf die übrigen Lampen aber nur den höchst unbedeutenden, sogar *wohlthätigen* Einfluss ausüben kann, dass der, so lange von dem nun unterbrochenen Nebendrahte absorbirt gewesene Stromtheil sofort dem Hauptdrahte zurück gegeben wird.

Die erforderliche Sicherheit, welche die frühere Methode entbehrte und desshalb ihre Concurrenz mit der Gasbeleuchtung unmöglich machte, ist also in dem Edison'sche Project vollständig garantirt, und so sollte man meinen, dass der praktischen Verwendung desselben Nichts mehr im Wege stehe, nachdem Edison auch die *andere* Hauptbedingung — eine zweckmässige *Lampe* — bereits zur vollständigen Befriedigung gelöst zu haben scheint!

Dies ist jedoch leider nicht so; vielmehr stellen sich der praktischen Anwendung dieser Methode noch andere Schwierigkeiten und Hindernisse entgegen, die selbst Edison nicht richtig gewürdigt zu haben scheint.

Wir wollen versuchen, diese Hindernisse hier näher zu beleuchten und ihre Bedeutung uns klar zu machen.

Der elektrische Telegraph und seine äussere Einrichtung, seine hunderte von Meilen langen Leitungsdrähte, durch die uns mit der grössten Zuverlässigkeit Nachrichten aller Art übermittelt werden etc., ist uns etwas so Alltägliches geworden, dass wir aus den uns entgegentretenden Erscheinungen und Umständen naturgemäss die Meinung bilden, dass der elektrische Strom durch den *längsten* Draht ohne alles Hinderniss hindurch gehe, und, gleichviel, ob *eine* oder *hundert* Meilen lang, in unbeeinträchtigter Stärke am entfernten Ziele anlange.

Diese sehr allgemein verbreitete, jedoch durchaus falsche Vorstellung von der Fähigkeit des elektrischen Stromes hat schon so manchen sonst tüchtigen Menschen verleitet, all' seine Habe und Arbeitskraft der eingebildeten Erfindung einer sogenannten elektro-magnetischen Kraftmaschine zu opfern, um dann die Enttäuschung zu erleben, dass seine Maschine, anstatt die erwartete grosse Kraft zu entwickeln, sich nicht rückt und rührt!

Der elektrische Telegraph verdankt seine Existenz zum grössten Theil dem Umstande, dass ein *äusserst schwacher Strom* seinem Zwecke vollständig genügt!

Wäre ein nur einigermaassen kräftiger Strom erforderlich, um die betreffenden Apparate in Thätigkeit zu setzen, so würde, durch diesen Umstand allein, die Anwendbarkeit des Telegraphen ganz ausserordentlich in Frage gestellt werden, denn entweder müsste dann der Draht, der jetzt hunderte von Meilen lang sein darf, auf eine ganz geringe Entfernung, vielleicht bis auf eine einzige Meile, reducirt werden, oder er müsste eine enorme Dicke, oder der Krafterzeuger (Batterie) eine enorme Kraft haben.

Der verhältnissmässig starke Strom aber, den eine Telegraphen-Batterie in einem *kurzen* Draht, etwa nur 100 Fuss lang, zu erzeugen vermag, wird in dem viele Meilen langen Draht durch den um soviel Mal vergrösserten *Widerstand* desselben so ausserordentlich geschwächt, dass, weit entfernt, den Telegraphen-Apparat direct in Thätigkeit setzen zu können, ein besonderer, äusserst empfindlicher Apparat, das Relais, an der Empfangs-Station angewendet werden muss, um eine zweite, dort aufgestellte Lokal-Batterie zur Unterstützung einzuschalten, die dann erst den eigentlichen Telegraphen-Apparat in Thätigkeit setzt.

Noch klarer dürfte uns die Bedeutung des Widerstandes der Drahtleitung durch folgende Beispiele werden.

Leitet man z. B. durch einen *starken* Kupferdraht, der etwa $\frac{1}{8}$ Zoll dick, und hundert Fuss lang sei, einen starken Strom einer Batterie von 10 Zellen, und controllirt die Stromstärke vermittelst eines eingeschalteten Galvanometers; verlängert man dann den Draht um das Doppelte, also auf zweihundert Fuss, so zeigt das Galvanometer eine Schwächung des Stromes an, die jedoch nicht bedeutend ist, und, je nach dem Verhältniss der Batterie zur Dicke des Leitungsdrahtes, vielleicht höchstens $\frac{1}{4}$ beträgt, so dass noch etwa $\frac{3}{4}$ oder noch mehr der ursprünglichen Stromstärke übrig bleibt.

Da nun die Vermehrung der Zellen der Batterie auch eine entsprechende Verstärkung der Stromerzeugung zur Folge hat, so sollte man erwarten, dass im vorliegenden Falle eine Zellenvermehrung um $\frac{1}{4}$, also auf 13 statt 10, die durch die Drahtverlängerung verursachte Stromschwächung von $\frac{1}{4}$ wieder zur ursprünglichen Stärke herstellen müsse. Dies tritt jedoch nicht ein, sondern die volle Stromstärke wird im vorliegenden Falle erst dann wieder hergestellt sein, wenn auch die Zahl der Zellen *verdoppelt* ist, also 20 beträgt!

Gehen wir wieder zurück und lassen es bei der ursprünglichen Zellenzahl 10, versuchen dagegen den Stromverlust durch entsprechende *Verdickung* der Leitung auszugleichen und verstärken zu diesem Zwecke *den* Theil der Drahtleitung, durch welchen die Stromschwächung verursacht wurde, nämlich einhundert Fuss der ganzen Leitung, während wir die ersten hundert Fuss in ihrer ursprünglichen Dicke belassen. Verstärken wir die hinzugekommenen hundert Fuss z. B. durch einen zweiten Draht von gleicher Länge und Dicke, den wir neben denselben legen und mit ihm von einem Ende bis zum anderen leitend verbinden, so zeigt uns das Galvanometer eine Zunahme der Stromstärke an. Obgleich nun diese Verstärkung nicht bedeutend ist, so sollten wir nach diesem Erfolge doch erwarten, dass durch fortgesetzte Verstärkung dieser einhundert Fuss endlich der Punkt erreicht werden müsste, wo die ursprüngliche Stromstärke wieder eintritt. Dies ist jedoch nicht so. Der Strom kommt zwar der ursprünglichen Stärke immer näher und näher, je mehr die zweiten hundert Fuss verstärkt werden, kann diese aber *niemals ganz erreichen*, selbst wenn die Leitung armesdick oder noch dicker würde!

Nur wenn auch gleichzeitig die erste Hälfte der Drahtlänge verdickt wird, kann die ursprüngliche Stromstärke wieder erhalten werden.

Haben wir nun aus diesen Beispielen eine klare Vorstellung von der Bedeutung des Widerstandes gewonnen, der dem elektrischen Strome durch die Beschaffenheit der Drahtleitung geboten wird, so bedürften wir nur noch einiger praktischer Versuche zur Feststellung des positiven Werthes dieses Widerstandes, um uns die grossen Schwierigkeiten klar zu machen, die der Fortleitung eines *starken* elektrischen Stromes durch eine Drahtleitung von mehreren oder vielen tausend Fuss Länge entgegenstehen. Und in der That ist eine *enorme* Drahtdicke und gleichzeitig ein enorm starker Stromerzeuger dazu erforderlich!

Nun hat aber Edison's Zweigstrom-Project neben den Eingangs beschriebenen Vorzügen den grossen Fehler, dass nicht allein nicht der volle vorhandene Strom, sondern sogar nur ein *sehr geringer Theil* desselben für die Lichterzeugung verwendet werden kann. Ist der Hauptstrom nicht so stark, dass der für die Lichterzeugung in einer Lampe erforderliche Stromtheil fast verschwindend klein gegen denselben ist, so würde — falls nicht eine grosse Regelmässigkeit in der gleichzeitigen Thätigkeit einer bestimmten Anzahl Lampen stattfindet — die Beeinflussung des Hauptstromes, die wieder reactiv auf die einzelnen Lampenströme wirkt, so bedeutend sein, dass die sonst höchst sinnreiche Vorrichtung zur Regulirung der Stromstärke in der Edison'schen Lampe mit glühender Platinaspirale (siehe "Techniker" No 14) sich als *unzureichend* erweist, und das Licht ein Mal zu schwach und das andere Mal zu stark wäre, so dass der Platinadraht dennoch zum Schmelzen und die Thätigkeit der Lampe dadurch zum Stillstande gebracht würde.

Aber selbst um das Edison'sche Glüh-Licht hervorzubringen, resp. die Platinaspirale hinreichend zu erglühen, ist schon ein *ziemlich starker* elektrischer Strom erforderlich!

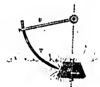
Edison ist nicht der Erste, der den Versuch gemacht hat, den elektrischen Strom zur Beleuchtung in ausgedehntem Maassstabe und auf grosse Entfernungen zu benützen. Aber seine Vorgänger (Lontin, Gramme etc.) waren ihm darin *überlegen*, dass sie wenigstens den wegen der grossen Circulationslänge höchst kostbaren Strom in seiner *vollen Stärke* für ihre Lichterzeugung ausbeuteten. Alle solche Versuche scheiterten aber dennoch an den grossen Schwierigkeiten der Hervorbringung eines genügend starken elektrischen Stromes auf grosse Entfernungen, resp. der unverhältnissmässigen Kostspieligkeit desselben. Einen wie grossen Rückschritt macht daher Edison mit seinem Zweigstrom-Project, welches unter Umständen vielleicht noch *weniger als den hundertsten Theil* des vorhandenen Stromes für die Lichterzeugung verwendbar werden lässt!

17

In der That muss daher die praktische Ausführbarkeit dieses Projects, wenigstens im grösseren Maassstabe, für *absolut unmöglich* angesehen werden, und so lange es Herrn Edison nicht gelingt, dieses Haupthinderniss zu beseitigen, werden seine in grösserem Maassstabe auszuführenden Versuche von vollständigem Fehlschlage begleitet sein. Thatsache ist, dass die seit Jahr und Tag versprochene elektrische Beleuchtung von Menlo Park bis dato noch nicht stattgefunden hat. In unserer nächsten Nummer werden wir nun Edison's Neuerungen auf dem Gebiete der dynamo-elektrischen Maschinen, sowie seine Glühlicht-Lampen des Näheren beleuchten und den Nachweis zu liefern suchen, dass er, mit Ausnahme mehrerer sinnreichen Lampen-Constructionen, in Bezug auf Strom-Maschinen, soweit diese jetzt bekannt sind, ein glänzendes Fiasco gemacht hat.

LAMPE VARLEY

La lampe Varley, brevetée en 1876, se compose d'un crayon ou charbon de cornue, de forme bizarre, reposant sur un galet qui est animé d'un mouvement de rotation dans le sens indiqué par la flèche. Le charbon rectiligne presse par son poids en proportion de son usure. F.

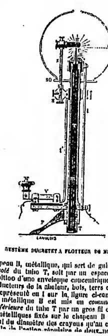


V. Levier pivotant auquel est attaché le charbon T.
T. Charbon positif en forme de demi-cercle venant butter par son propre poids contre le charbon N.
N. Charbon négatif servant de butée et animé d'un mouvement rectiligne.

—

LAMPE DUCRETET

La lampe Ducretet, dont nous donnons plus bas la description, réalise le principe du système Werdermann d'une façon ingénieuse, mais prévue, à ce qu'on nous dit, dans un des brevets de l'inventeur.



SYSTÈME DUCRETET A FLOTTEUR DE MERCURE

Le chapeau B, métallique, qui sert de guide aux crayons G, est *isolé* du tube T, soit par un espace libre, soit par l'interposition d'une enveloppe concentrique de corps mauvais conducteurs de la chaleur, bois, terre cuite, verre, etc.; espace représenté en I sur la figure ci-contre première. Le chapeau métallique B est mis en *communication avec la partie inférieure* du tube T par un gros fil conducteur *t*. Les guides métalliques fixés sur le chapeau B sont mobiles et dépendent du diamètre des crayons qu'on emploie.

Par suite de l'action répulsive de deux portions consécutives d'un même courant, mais surtout par suite *du contact imparfait* du crayon G contre le bloc B (de charbon de cornue), il se produit un très-petit arc, puis (comme dans toutes les lampes électriques) le crayon rougit sur une certaine longueur que limite le contact métallique du chapeau B. Le crayon s'use au fur et à mesure de sa combustion, constamment amené au point d'appui B par la poussée du mercure. — La chaleur intense du crayon se communique de suite au chapeau métallique B, puis trouve un écoulement rapide par le conducteur métallique *t* qui y est fixé. Le calorique tend donc à arriver, par l'intermédiaire du conducteur *t*, à la partie inférieure du tube métallique T et à chauffer le mercure.

L'énergie du calorique développé est d'autant plus grande que le charbon qui flotte est le petit charbon qui se brûle et que le gros est celui qui sert de butoir.

La difficulté de se débarrasser de la chaleur est fort gênante. C'est une des raisons qui empêcheront probablement cet appareil de sortir du laboratoire, où sa place est marquée d'avance comme beaucoup d'appareils sortis des ateliers de cet habile ingénieur.

14/20/2

Manufacturer & Builder Jan 1880

The Electric Lamp of Edison.

We take pleasure in representing on this page the form of lamp which Mr. Edison's researches have led him at last to adopt.

It appears that he soon found that the electric arc, so called, (which is the intensely luminous spark that flashes through the air between two carbon points placed close together), does not satisfy the requirements, and this for several reasons: 1st. It is altogether too intense for domestic use. 2d. It is not adapted for subdivision, as proved by the many futile attempts to accomplish this. 3d. It is difficult to keep it steady, as proved by all the different devices applied to the electric lamps, with and without regulating clock-work, none of which thus far have fully met the requirements.

Mr. Edison discards these lamps altogether, and first [used] platinum, which is brought by the electric current to the state of incandescence in which it gives a light that, while strong enough for illumination, is at the same time not so intense as to produce a disagreeable glare, as is the case with the ordinary electric lights thus far used. But the use of platinum, or some platinum alloy, which is subsequently used, involves great expense, as it belongs to the rare metals; while the manufacture of millions of lamps, which will be needed to supply the demand when once the electric light is introduced, would certainly raise the price of that scarce and already too expensive material. Therefore, he published some time ago a request to miners, asking them to give attention to the finding of more platinum. This appeal resulted in showing that, if needed, more platinum would be forthcoming, as was proved by an exhibition of results made at the close of the recent meeting of the American Association for the Advancement of Science, at Saratoga, N. Y., where Prof. Forsyth Barker, of Philadelphia, explained a large number of samples, which showed that in this case the demand could be supplied, even if it increased very far above the present limits, which are very contracted, as this precious metal is not suitable for ornaments, being by no means a handsome looking metal, (which makes gold and silver so attractive); neither is it used for coin, although Russia introduced some such coin several years ago. It is only used for those scientific and manufacturing purposes where its place cannot be supplied by anything else, hence the limited demand never stimulated increased production.

Now, however, Mr. Edison discards the incandescent platinum altogether, and uses nothing but carbon, which certainly is cheap and abundant enough; but he places it in a vacuum in order to prevent its combustion, which certainly would follow in the air, and that very rapidly too, as at the temperature required to make substances emit light, the affinity of carbon for atmospheric oxy

HISTORY OF ELECTRIC LIGHTING.

The near approach of the first public exhibition of Edison's long looked for electric light, announced to take place on New Year's Eve at Menlo Park, on which occasion that place will be illuminated with the new light, has revived public interest in the great inventor's work, and throughout the civilized world scientists and people generally are anxiously awaiting the result. From the beginning of his experiments in electric lighting to the present time Mr. Edison has kept his laboratory guardedly closed, and no authoritative account (except that published in the HERALD some months ago relating to his first patent) of any of the important steps of his progress has been made public—a course of procedure the inventor found absolutely necessary for his own protection. The HERALD is now, however, enabled to present to its readers a full and accurate account of his work from its inception to its completion.

A LIGHTED PAPER.

Edison's electric light, incredible as it may appear, is produced from a little piece of paper—a tiny strip of paper that a breath would blow away. Through this little strip of paper is passed an electric current, and the result is a bright, beautiful light, like the mellow sunset of an Italian autumn.

"But paper instantly burns, even under the trifling heat of a tallow candle!" exclaims the sceptic, "and how, then, can it withstand the fierce heat of an electric current?" Very true, but Edison makes the little piece of paper more infusible than platinum, more durable than granite. And this involves no complicated process. The paper is merely baked in an oven until all its elements have passed away except its carbon framework. The latter is then placed in a glass globe connected with the wires leading to the electricity producing machine, and the air exhausted from the globe. Then the apparatus is ready to give out a light that produces no deleterious gases, no smoke, no offensive odors—a light without flame, without danger, requiring no matches to ignite, giving out but little heat, vitiating no air, and free from all flickering; a light that is a little globe of sunshine, a veritable Aladdin's lamp. And this light, the inventor claims, can be produced cheaper than that from the cheapest oil. Were it not for the phonograph, the quadruplex telegraph, the telephone and the various other remarkable productions of the great inventor the world might well hesitate to accept his assurance that such a beneficent result had been obtained, but, as it is, his past achievements in science are sufficient guarantee that his claims are not without foundation, even though for months past the press of Europe and America has teemed with dissertations and expositions from learned scientists ridiculing Edison and showing that it was impossible for him to achieve that which he has undertaken.

HIS FIRST ATTENTION TO ELECTRIC LIGHTING.

When Edison began his experiments in September, 1878, he had just returned from the inspiring scenery of the Rocky Mountains, where he had been enjoying a little recreation after several months of hard labor. He was ripe for fields and enterprises new. A visit to a Connecticut factory where an electric light was used concentrated his thoughts on the subject of lighting by electricity, and he determined to attack the problem. Previous to this time, although he had roamed broadcast over the domain of electricity, wresting from it, as is well known, many of its hidden secrets, Edison had scarcely thought of the subtle fluid in connection with practical illumination. Now, however, he bent all his energies on the subject, and was soon deep in the bewildering intricacies of subdivision, magneto currents, resistance laws and the various other branches going to make up a system of lighting by electricity. The task before the young inventor was divisible into two parts.

First—The producing of a pure, steady and reliable light from electricity; and

Second—Producing it so cheaply that it could compete with gas for general illumination.

HE CHOOSES INCANDESCENCE.

Of the two systems before him—viz., voltaic arc and the incandescence system, Edison chose the latter as his field of operations. Prominent among the difficulties incident to incandescent lighting, it will be remembered, was the liability of the platinum (when that metal was used) to melt under the intense heat of the electric current, and the liability of the carbon, when that was employed, to gradually become disintegrated under the combined action of gases and the electric current.

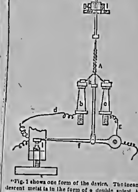
THE PLATINUM LIGHT.

As between platinum and carbon as the substance to be made incandescent, Edison took up platinum and devoted first his attention to the obtaining of some device to prevent the platinum from melting under the intense heat of the electric current. An ingenious and simple contrivance met the requirement. He arranged a small lever, about three inches long, so that the expansion of the platinum (caused by the heat) beyond a certain degree would close it, such closing making a new passage for the electric current and cutting it off from the incandescent platinum. When the latter contracted, as it did the moment the heat was lessened, the lever returned to its normal position and allowed the electric current to again pass through the platinum. By this device the inventor hoped to be able to keep the incandescent platinum always below its melting point. The contrivance is described in his first patent as follows:—

THE FIRST LIGHT.

"Electric lights have been produced by a coil or strip of platinum or other metal that requires a high temperature to melt, the electric current rendering the same incandescent. In all such lights there is danger of the metal melting. My improvement is made for regulating the electric current automatically passing through such incandescent conductor, and preventing its temperature rising to the melting point, thus producing a reliable electric light."

FIGURE 1.



"Fig. 1 shows one form of the device. The incandescent metal is in the form of a double spiral A, the two ends terminating upon the posts b, c, to which the conductors d, E, are connected. A circuit closing lever, f, is introduced in the electric circuit, the points of contact being at l, and there is a platina, or similar wire, k, connected with the lever, f, in the headpiece or other support, l. The current from a magneto machine is connected with the wires E and d. The current then flows from E to the post, c, thence around the platinum spiral to b, and is carried off by the wire, d. Now, when the rod, k, of platinum becomes heated to too great intensity its expansion closes the lever, f, and the current then passes from E, through f, and not through the spiral at all. In this way the lever cuts off the current every time the heat becomes too intense."

Numerous other devices of a similar character were tried and for a while they all worked satisfactorily, but the inventor finally discovered that the constant expansion of the platinum rod k and its pressure upon the lever f bent it so that it became unreliable and it was, therefore, abandoned.

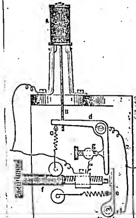
THE SECOND PLATINUM LAMP.

The next regulator was in the form of a diaphragm, which cut off the electric current from the platinum every time the diaphragm was pressed outward beyond a fixed limit by the heated air. The regulation thus produced was so rapid that the eye could not perceive any diminution in the strength of the current. But this also was inadequate in many respects. The next important modification in the light was the substitution for the platinum spiral of finely divided platinum incorporated with non-conducting material. When the electric current was passed through the combination the platinum particles became incandescent and the non-conducting material incorporated with them became luminous and increased the brilliancy. One advantage by this form not previously attained was that a very weak electric current produced a good light.

A ... BOBBIN LAMP.

After this followed a device for obtaining more light-giving surface, the platinum being wound in the form of a small bobbin, first having been coated with a non-conducting coating that was not injured by the heat. With this arrangement a new form of regulator was used. The lamp at this stage is shown in figure 2.

FIGURE 2.



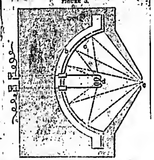
A is the incandescent bobbin, between the coils of which is a coating of magnesia. The top of the bobbin has a metallic cap connected to the lever, d. A spring, C, draws the rod, B, downward with considerable pressure, and this, in course, places pressure on the top of the bobbin, thus keeping the wire in contact with the upper end of the coil. The bobbin, A, expands as a whole by the heat and draws the rod, B, upward. This brings the lever attached upward and allows the lever, E, to come in contact with the screw, F, permitting the current to find a passage other than that afforded by the incandescent material.

The inventor next followed with a new regulator and a meter for measuring the amount of electricity used; also an automatic switch connecting the regulator with the ... in the machine for generating the electric current.

THE REFLECTOR LAMP.

The next was a unique idea, making the platinum give the light as it were by proxy. By means of a reflector he concentrated the heat rays of the platinum upon a piece of zircon, causing the latter to become luminous. Figure 3 shows this apparatus.

FIGURE 3.



A is a mass of non-conducting material, b is an air space, c is a polished reflector of copper coated with gold, d is a platinum-iridium spiral, which becomes heated by the passage of the electric current through it. E is a thin piece of zircon that receives the heat rays thrown off by the reflector, C, which heat rays bring up the zircon, E, to vivid incandescence, making it give out a light much more brilliant than the light of the platinum spiral, C. With this form Mr. Edison tried numerous experiments, and from time to time made many alterations and improvements, but eventually the apparatus was placed in the category of non-successes.

ANOTHER SPIRAL.

Realizing from the first the necessity of the light giving substance offering much resistance to the passage of the electric current—a necessity in extensive subdivision of the light—the inventor throughout his experiments kept a close watch for substances and forms that gave ... resistances. In figure 4 is shown a form of lamp disconnected from the regulating apparatus, which largely embodied the above requirement and for a time gave good results.

FIGURE 4.

A is a spiral of carbon with two terminals ... connecting with the wires leading to the machine for generating the current. This device was tried for several weeks, but did not, as a whole, give satisfaction.

EVERY MAN HIS OWN ELECTRIC LIGHTER.

Branching off from the line of investigation he had been previously following Mr. Edison at this time began experimenting with a view to having the light produced locally—i. e., arranging for each householder to become his own manufacturer of light, thus dispensing with mains and central stations. The apparatus which he used for this purpose is shown in figure 5:—

FIGURE 5.

R is an induction coil, such as are used by patent showmen at fairs and other places when they give electric shocks to inquiring sightseers at so much per shock. It is operated by two cells of battery, B, and wires lead from it to the glass tubing, T, from which the air has previously been extracted, and the passage of the electric current through the tubing gives out a light. This plan is analogous to what is known as the Geissler tube arrangement, the difference being in the form of the tube and the extreme smallness of the bore and also in the degree of vacuum produced. Mr. Edison succeeded by this arrangement in obtaining a light of several candle power with a moderately powerful induction coil. The light, however, was not the one sought after so persistently by the inventor, and so it took its place in that part of his laboratory occupied by inventions not in use.

OSMIUM-IRIDIUM.

Once more Mr. Edison made a departure. He moulded powdered metallic oxides in the form of sticks and subjected them to a very high temperature. In this connection he obtained very fine results from the native alloy of osmium-iridium called iridosmine, which alloy he used in the form of a powder enclosed in a tube of zircon. The electric current passing through the same brought it to a beautiful incandescence.

CARBON AND PLATINUM.

The inventor's next important move was the adoption of carbon in connection with platinum as the substances to be made incandescent. He caused a slender rod of carbon to rest upon another of platinum, the inferiority of contact between the two at their point of meeting producing a resistance to the passage of the electric current and causing the carbon to become highly incandescent, while the platinum attained only a dull red heat. The carbon rod was kept pressing upon the platinum by a weight ingeniously arranged. A dozen or more forms of this lamp were made; but, after all, the inventor was obliged to return to platinum as the substance most suitable, all things considered, for being made incandescent. For two months he worked at platinum day and night, only to find that platinum, as he had been using it, was entirely worthless for incandescent lighting. To many experimenters this would have proved a discouragement perhaps fatal, but it had the effect only of increasing Edison's determination.

THE CRACKS IN PLATINUM.

After scores of new experiments he arrived at the true causes of the defects and hastened to apply the remedy. I have found, he writes, that when wires or sheets of platinum, iridium or other metallic conductors of electricity that fuse at a high temperature are exposed to a high temperature near their melting point in air for several hours by passing a current of electricity through them and then are allowed to cool, the metal is found to be ruptured, and under the microscope there are revealed myriads of cracks in various directions, many of which reach nearly to the centre of the wire. I have also discovered that, contrary to the received notion, platinum or platinum and iridium alloy loses weight when exposed to the heat of a candle; that even heated air causes it to lose weight; that the loss is so great a hydrogen flame is tinged green. After a time the metal falls to pieces; hence wire or sheets of platinum or platinum and iridium alloy as now known in commerce are useless for giving light by incandescence—

First—Because the loss of weight makes it expensive and unreliable and causes the burner to be rapidly destroyed;

Second—Because its electrical resistance changes by loss in weight, and its light-giving power for the total surface is greatly reduced by the cracks or ruptures.

The melting point also is determined by the weakest spot of the metal.

PLATINUM IN VACUO.

By my invention or discovery I am able to prevent the deterioration of the platinum or its alloys by cutting off or intercepting the atmospheric action. A spiral wire or other forms of platinum is placed in a glass tube or bulb, with the wire near its ends passing through and sealed in the glass, and the air is exhausted from the glass. The platinum wires of the spiral are then connected to a magneto-electric machine or battery, the current of which can be controlled by the addition of resistance. Sufficient current is allowed to pass through the wire to bring it to about 150 degrees Fahrenheit. It is then allowed to remain at this temperature for ten or fifteen minutes. While thus heated both the air and gases confined in the metal are expelled by the heat, or withdrawn by the vacuum action.

While this air or the gases are passing out of the metal the mercury pump is kept continually working.

After the expiration of about fifteen minutes the current passing through the metal is augmented so that its temperature will be about 300 deg. Fahrenheit, and it is allowed to remain at this temperature for another ten or fifteen minutes.

The mercury pump is to be worked continuously and the temperature of the spiral raised at intervals of ten or fifteen minutes until it attains vivid incandescence and the glass is contracted where it has passed to the pump and melted together.

BRILLIANT RESULTS.

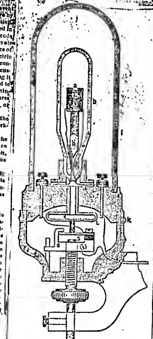
The wire is now in a perfect vacuum and in a state heretofore unknown, for it may have its temperature raised to a most dazzling incandescence, emitting a light of twenty-five standard candles, whereas before treatment the same radiating surface gave a light of only about three standard candles. The wires after being thus freed from gases are found to have a polish exceeding that of silver and obtainable by no other means. No cracks can be seen even after the spiral has been raised suddenly to incandescence many times by the current, and the most delicate balance fails to show any loss of weight in the wire even after it is burning for many hours continuously. I have further discovered that if an alloy of platinum and iridium is coated with the oxide of magnesia and subjected to the vacuum process described, a combination takes place between the metal and the oxide, giving the former remarkable properties. With a spiral having a radiating surface of 3-16 of an inch light equal to that given by forty standard candles may be obtained, whereas the same spiral, not coated by my process, would melt before giving a light of four candles. The effect of the oxide of magnesia is to harden the wire to a surprising extent and render it more refractory. A spiral made of this wire is elastic and springy when at high incandescence. I have found that chemically pure iron and nickel drawn in wires and subjected to the vacuum process may be made to give a light equalling that of platinum in the open air. Carbon sticks also may be freed from air in this manner and be brought to a temperature where the carbon becomes pasty and on cooling it is homogeneous and hard.

THE FIRST PLATINUM VACUUM LAMP.

About this time another truth dawned upon the inventor—namely, that economy in the production of light from incandescence demanded that the incandescent substance should offer a very great resistance to the passage of the electric current. Concerning this the inventor writes:—"It is essential to reverse the present practice of having lamps of but one or two ohms [electrical units] resistance and construct lamps which, when giving their proper light, shall have at least two hundred ohms resistance."

The lamp, as it stood at this stage of the inventor's progress, is shown in figure 6.

FIGURE 6.



a is the burner or incandescent platinum in the shape of a bobbin supported within the vacuum tube, b, by a rod, b', of the same material as the bobbin. The vacuum tube, b, is sustained by the case, k, and around said tube, b, is a glass globe, l. Within the case, k, is a flexible metallic aneroid chamber, l, that opens into the glass case, so that the air, when expanded by the heat, can pass into the aneroid chamber and give motion to the flexible diaphragm, x, and parts connected therewith. When the current circulating around the bobbin, a, becomes too intense and heats the latter too highly the air within the glass case, l, is expanded and bulges downward by the diaphragm, x, and the pin thereon pressing upon the spring, 5, and separating said spring from the block, 6, breaks the circuit to the burner. The temperature within the globe, l, lowers immediately and the parts return to their normal position, closing the circuit through the burner to 5 and 6. This opening and closing of the circuit is but momentary, and, therefore, the uniform brilliancy of the light is not affected and there is no danger of the burner becoming too highly heated.

PERFECTING THE MACHINERY.

The lamp, after these latter improvements, was in quite a satisfactory condition, and the inventor contemplated with much gratification the near conclusion of his labors. One by one he had overcome the many difficulties that lay in his path. He had brought up platinum as a substance for illumination from a state of comparative worthlessness to one well nigh perfection. He had succeeded, by a curious combination and improvement in air pumps, in obtaining a vacuum of nearly one millionth of an atmosphere; and he had perfected a generator or electricity producing machine (for all the time he had been working at lamps he was also experimenting in magneto-electric machines) that gave out some ninety per cent in electricity of the energy it received from the driving engine. In a word, all the serious obstacles toward the success of incandescent electric lighting, he believed, had melted away, and there remained but a comparatively few minor details to be arranged before his laboratory was to be thrown open for public inspection and the light given to the world ... .

A GREAT DISCOVERY.

There occurred, however, at this juncture a discovery that materially changed the system and gave a rapid stride toward the perfect electric lamp. Sitting one night in his laboratory reflecting on some of the unfinished details, Edison began abstractedly rolling between his fingers a piece of compressed lampblack mixed with tar for use in his telephone. For several minutes his thoughts continued far away, his fingers in the meantime mechanically rolling out the little piece of tarred lampblack until it had become a slender filament. Happening to glance at it the idea occurred to him that it might give good result as a burner if made incandescent. A few minutes later the experiment was tried, and, to the inventor's gratification, satisfactory, although not surprising results were obtained. Further experiments were made, with altered forms and composition of the substance, each experiment demonstrating that at last the inventor was upon the right track.

A COTTON THREAD.

A spool of cotton thread lay on the table in the laboratory. The inventor cut off a small piece, put it in a groove between two clamps of iron and placed the latter in the furnace. The satisfactory light obtained from the tarred lampblack had convinced him that filaments of carbon of a texture not previously used in electric lighting were the hidden agents to make a thorough success of incandescent lighting, and it was with this view that he sought to test the carbon remains of a cotton thread. At the expiration of an hour he removed the iron mould containing the thread from the furnace and took out the delicate carbon framework of the thread—all that was left of it after its fiery ordeal. This slender filament he placed in a globe and connected it with the wires leading to the machine generating the electric current. Then he extracted the air from the globe and turned on the electricity.

Presto! a beautiful light greeted his eyes. He turns on more current expecting the fragile filament instantly to fuse; but no, the only change is a more brilliant light. He turns on more current, and still more, but the delicate thread remains entire. Then, with characteristic impetuosity and wondering and marvelling at the strength of the little filament, he turns on the full power of his machine and eagerly watches the consequence. For a minute or more the tender thread seems to struggle with the intense heat passing through it—heat that would melt the diamond itself—then at last it succumbs and all is darkness. The powerful current had broken it to

...and not before it had emitted a light of ... Eagerly the inventor hastened to examine under the microscope this curious filament, apparently so delicate, but in reality much more infusible than platinum, so long considered one of the most infusible of metals. The microscope showed the surface of the filament to be highly polished and its parts interwoven with each other.

THE PAPER FOUND.

It was also noticed that the filament had obtained a remarkable degree of hardness compared with its fragile character before it was subjected to the action of the current. Night and day, with scarcely rest enough to eat a hearty meal, or catch a brief repose, the inventor kept up his experiments, and from carbonizing pieces of thread he went to splinters of wood, straw, paper and many other substances never before used for that purpose. The results of his experiments showed that the substance best adapted for carbonization, and the giving out of incandescent light, was paper, preferably thick like card board, but giving good results even when very thin. The beautiful character of the illumination and the steadiness, reliability and non-fusibility of the carbon filament were not the only elements incident to the new discovery that brought joy to the heart of Edison. There was a further element—not the less necessary because of its being hidden—the element of a proper and uniform resistance to the passage of the electric current.

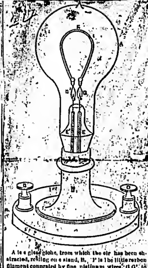
The inventor's efforts to obtain this element had been by far the most laborious, say, in the history of his work from the time he undertook the task, and without it absolute success in electric incandescent illumination could not be predicated, even though all the other necessary properties were present in the fullest degree.

Passing over the scores of experiments made since the discovery that the carbon framework of a little piece of paper or thread was the best substance possible for incandescent lighting, we come to consider the way in which the same is prepared at the present time in the laboratory.

MAKING THE PAPER CARBON.

With a suitable punch there is cut from a piece of "Bristol" cardboard a strip of the same in the form of a miniature horseshoe, about two inches in length and one-eighth of an inch in width. A number of these strips are laid likewise in a wrought iron mould about the size of the hand and separated from each other by tissue paper. The mould is then covered and placed in an oven, where it is gradually raised to a temperature of about six hundred degrees Fahrenheit. This allows the volatile portions of the paper to pass away. The mould is then placed in a furnace and heated almost to a white heat, and then removed and allowed to cool gradually. On opening the mould the charred remains of the little horseshoe cardboard are found. It must be taken out with the greatest care, else it will fall to pieces. After being removed from the mould it is placed in a little globe and attached to the wires leading to the generating machine. The globe is then connected with an air pump, and the latter is at once set to work extracting the air. After the air has been extracted the globe is sealed, and the lamp is ready for use. Figure 7 shows the lamp complete:—

THE PERFECTED LAMP—FIGURE 7.



A is a glass globe, from which the air has been extracted, resting on a stand, B. F is the little carbon filament connected by fine platinum wires, C C', to the wires, E E', leading to the screw posts, D D', and thence to the generating machine. The current, entering at D, passes up the wire E to the platinum clamp, C; thence through the carbon filament F to C', down the wire E' to the screw post D'; thence to the generating machine. It will be noticed, by reference to the complete lamp in figure 7, that it has no complex regulating apparatus, such as characterized the inventor's earlier labors. All the work he did in regulators was practically wasted, for he has lately realized that they were not at all necessary—no more so than a fifth wheel is to a coach.

REGULATED AT THE MAIN, LIKE GAS—CHEAP.

He finds that the electricity can be regulated with entire reliability at the central station, just as the pressure of gas is now regulated. By his system of connecting the wires the extinguishment of certain of the burners effects the others no more than the extinguishment of the same number of gas burners affects those drawing the supply from the gas mains. The simplicity of the completed lamp [illegible] certainly to have arrived at the highest point. Edison asserts that it is scarcely possible to simplify it more. The entire cost of constructing them is not more than twenty-five cents.

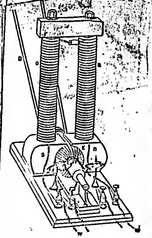
EASY METAMORPHOSIS.

The lamp shown in figure 7 is a table lamp. [illegible] chandelier it would consist of only the vacuum globe and the carbon filament attached to the chandelier and connected to the wires leading to the generating machine in a central station, perhaps a mile away, the wires being run through the gas pipe, so that in reality the only change necessary to turn a gas jet into an electric lamp is to run wires through the gas pipe, take off the jet and set the electric lamp in the latter's place. Although plans have been fully consummated for general [illegible] the outline of the probable system to be adopted is the locating of a central station in cities in such a manner that each station will supply an area of about one-third of a mile. In each station there will be, it is contemplated, one or two engines of immense power, which will drive several generating machines, each generating machine supplying about fifty lamps.

THE GENERATING MACHINE.

Mr. Edison's first experiments in machines for generating the electric current did not meet with success. His primal apparatus was in the form of a large tuning fork, constructed in such a way that its ends vibrated with great rapidity before the poles of a large magnet. These vibrations could be produced with comparatively little power. Several weeks of practice proved, however, that the machine was not practical, and it was laid aside. Then followed a number of other forms, leading up gradually to the one at present used. Bearing in mind the principle common to all magneto-electric machines—viz., that the current is produced by the rotation of magnets near each other—it will not be difficult to understand, in a general way, how this machine operates. Figure 8 shows the generating or Faradic machine, as Edison terms it, in honor of Faraday, complete:—

THE GENERATING MACHINE—FIGURE 8.



[illegible] are two upright iron columns, three feet high and eight inches in diameter, wound with coarse wire and resting upon the [illegible] and a, which form its magnetic poles. This part of the apparatus is called the field of force magnet. Fixed on an axle, so as to freely revolve between the poles a and a, is a cylindrical armature of wood, e, wound parallel to its axes with fine iron wire. When this cylinder or armature is made to revolve rapidly between the magnetic poles a and a, by means of the belt B, driven by an engine (not shown in the cut), there is generated in the wire surrounding the armature a strong current of electricity, which are carried off by the wires, W W, to the electric lamps.

A DOMESTIC MOTOR.

By constructing the machine in the form shown in figure 9 there is obtained an electric motor capable of performing light work, such as running sewing machines and pumping water. It forms part of the inventor's system and may be used either with or without the electric light. To run an ordinary sewing machine it requires only as much electricity as is necessary to give out one electric light of the strength of a common gas jet. To put it in operation on a sewing machine the housewife has merely to attach it by a little belt at A with the wheel of the sewing machine, and turn on the electricity by touching a little knob conveniently attached. The cost is the same as if she was burning one electric light.

THE ELECTROMETER.

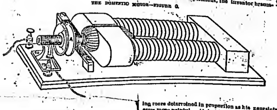
The apparatus for measuring the amount of electricity used by each householder is a simple contrivance consisting of an electrolytic cell and a small coil of wire, appropriately arranged in a box, the latter being of about half the size of an ordinary gas meter, and like a gas meter it can be placed in any part of the house. The measurement is obtained by the deposit of copper particles on a little plate in the electrolytic cell, each deposit being caused by the electric current passing through the cell. At the end of any period, say one month, the plate is taken by the inspector to the central office, where the copper deposit is weighed and the amount of electricity consumed determined by a simple calculation.

In addition to the various parts of the system above described, there are a number of other details, not so important to be above as those of which sketches have been given, but nevertheless essential to make up the complete plan of economical electrical illumination. A description of these latter will not be attempted, as a proper understanding of them involves a technical knowledge of the laws of electricity. The entire system embraces an amount of work so extensive that one naturally wonders how a single man in such a brief space of time as fifteen months could possibly have planned and perfected it all. And surprise becomes greater when it is considered that during this period Edison found time to make other inventions. A sextuplex telegraph, or apparatus for sending six messages on one telegraph wire in opposite directions simultaneously, saw life during the progress of the electric light, patents for the same having only just been issued. Several new and important improvements in his chalk telephone, by which the efficiency of that invention is greatly increased, also attest his industry and versatility of genius.

POLYFORM.

But perhaps the latter quality is more strikingly exhibited in his polyform or preparation by which he is enabled to bid defiance to sick headaches, neuralgia and other nervous diseases, and to make himself largely independent of physicians in times of ailment. The polyform grew out of necessity. Being considerably afflicted with neuralgia and obtaining no relief from his physician, Edison set about becoming his own doctor. His chemical laboratory, one of the most complete in the United States, furnished him an ample field from which to draw. Experiment followed experiment, the inventor becom-

THE DOMESTIC MOTOR—FIGURE 9.



ing more determined in proportion as his neuralgia grew more painful. At first he obtained a combination of chemicals, a slight application of which to...

THE [illegible] LIGHT. Dec [illegible] 79

The electric light at [illegible] has [illegible] at [illegible] for [illegible] a [illegible] brilliant light, so pleasant to the eye that it may be studied closely. In his laboratory, which, by the way, is a large establishment running night and day, with perhaps fifty employees, the light is distributed equally all over the building. The little exhausted receiver lamp has the highest illuminating power, but the open flame is a very good light. In the small vacuum light there is hardly any heat, but the light is far purer and more steady. The shape now is that of a horseshoe, but there is no reason why it might not be a circle, a crescent, a triangle, or any other form which personal taste might prefer. The light could be readily built into any form or design of art and made to be a picture.

The problem with Mr. Edison seems to have been not so much the production of sufficient electric force as that of a cheap lamp. Not long ago he was looking for iridium or platinum points to interrupt the current at each light. But these two metals are rare and costly, and probably there is not enough of them in the world to supply a single great city. The carbon point seems to have been agreed upon as the best, but even that was costly. It lasted well, as the London experiments showed, but it needed very nice handling and adjustment. Mr. Edison gets a cheap carbon point by only burning a slender thread of Bristol board at a high heat, and finds that the slender thread or horseshoe which results is tough enough to handle well and can be fitted easily across the electric current. The point which he seeks is an incandescent burner, so simple and so cheap that it can be easily managed by any intelligent person. One of these burners has been in use twenty days of twenty-four hours each, and is still one of the strongest lights on the main floor of the laboratory. Manufactured in quantities, such burners would cost about the one hundredth of a cent, and could be replaced at any time by any person of ordinary deftness of finger. So far as the burner is concerned, Mr. Edison has certainly achieved a success. He has found a cheap thing, which will answer every purpose, and got rid of all iridium, platinum and elaborate carbon points.

But all this does not fully settle the question of cheap light. Mr. Edison works a large manufactory and lights a number of residences and streets by the power of an eighty-horse power engine. He is confident that the system can be extended indefinitely and that with the touch of a thumb at a central office the whole city can be made brilliant in a light which is almost a true sunshine. But there are two difficulties which remain. One is the amount and cost of the power required to produce the electricity—modified by the deduction that in revolving the magnets it may at the same time work other machinery. The other doubt is as to whether the electric current can be so distributed through "all out of doors" as to be certain in its working. The cutting of a single wire might place a whole section of a city in darkness just as the break of a gas main would do the same thing. In the electric [illegible] the thread is more slender, the intelligence required more exacting, but that is the fault of all inventions. Every advance of science requires a keener intelligence and a closer watch. In the Capitol at Washington a single pressure on one key down in the basement sets all the gas blazing, but the patient detail necessary to produce the result is unconsidered. An interruption at any one point is an interruption to all beyond it, and that may be an [illegible] difficulty which Mr. Edison will

The difficulty of subd[illegible]ing the electric current is supposed to have been overcome by making a vacuum in every lamp. He has neither oxygen, nitrogen, hydrogen or carbon as part of his fuel. The light passes from point to point of carbon, but there is no oxygen to consume his carbon. He gets light without heat. The flame is purely electric, but it burns nothing, for carbon will not burn unless it comes in contact with oxygen.

Art and Scientific Entertainments.

No city of the size of Newark has so many amusements and social entertainments. The greater number are given for the benefit of churches, Sunday Schools and local charities. The most of them are of the lightest possible character; pleasant, innocent and easily managed, but not often instructive. They have interfered largely with costlier and professional amusements, and very seriously with lectures, concerts and other forms of entertainment that are solid and instructive. These efforts to sustain institutions by means of dollars picked up from the general public, praiseworthy as they must be considered to be under the circumstances, have retarded the building of such a dramatic temple as may be found in every other city of any pretensions, and perhaps other artistic and even more useful additions to the metropolis, but it is a comfort to find that this season there has been some encouragement extended to worthy efforts which have hitherto been received with chilling indifference.

Five lectures have been delivered here on Ancient Art, with very fair success, and the more so as the lecturer was but little known in our community. They were not, in all respects, new; much of the information given is available in books, but they revived memories of past studies with some, and they were really fresh and instructive to a much larger class. Two lectures were given by another gentleman, on Paris, with a large number of stereopticon views, and, as with these, much historical information was pleasantly condensed, they were also profitable to those who heard them. Then, with many misgivings, Professor Proctor was invited to give two lectures on astronomy, and the nearly-filled house was a most gratifying surprise. There can be no doubt that his second lecture to-morrow night will be even better attended, for his subject is one of universal interest. At this time, also, we find art appealing to our citizens in the shape of a gallery of paintings from the easels of sixty of our best living artists. It cannot be supposed that that will lack appreciation in a city that counts so many elegant churches filled with educated congregations. Art in such choice as we see it there appeals to every pure taste and sensibility; it develops the affections and the love of the beautiful. It is not every one who can afford to buy a fine oil painting, but when Newark arrives to that point of prosperity and to that artistic culture which will enable it to permanently sustain an art gallery it will do as much towards the development of refined public taste as it has heretofore done in developing the homelier industries by which its people earn their daily bread. In these and in all other worthy lines of effort, the word spoken in season should never be refused, and with all the multitudinous efforts made to sustain churches and charities, there should be a continuation of that patronage towards worthy forms of popular instruction by which alone they can be drawn to our good city.

EDISON'S ELECTRICITY.

Washington Post

MENLO PARK ILLUMINATED WITH THE NEW LIGHT.

Dec 25 1879

Complete Success of the Carbon Paper Slip Illuminator—Scenes at the Home of the Great Inventor—The Death-Knell of Gas Companies.

Special Dispatch to THE POST.

MENLO PARK, N. J., Dec. 24.—This little village was illuminated with Prof. Thomas A. Edison's electric light this evening. Only four outdoor lamps were in operation, but electric burners to the number of twenty-eight were distributed in a dozen houses and the new light was pronounced a perfect success. It was demonstrated by illumination that the light of each of the so-called burners was fully equal to that produced by the ordinary gas-jet in the street-lamp or dwelling-house. Only two electric generators were in use to-day to supply the twenty-eight burners which were in operation, but with additional or more powerful generators the intensity of the light, Mr. Edison said, could be increased. A third generator will be finished in a day or two, and then a dozen or more additional burners will be set going. There was a marked difference between the light of the carbon paper burners at Menlo Park and the intense dazzling light given by the electric lamps which have for some time past been used in New York and other cities. The painful scintillation of the latter, caused by innumerable sparks chasing each other over the metal, instead of the carbonized retainer, is entirely avoided. After the visitors had witnessed the effect of the illumination from the lamps and from the outside of the houses, they were permitted to enter several of the private residences and judge of the utility of the new light for household purposes. One gentleman had an electric light in one of the sleeping rooms of his house. He said that the only fault he found with the light was that it was too bright. Said he, "I must either allow it to remain on full head or turn it off entirely. There is no intermediate point, but I presume Mr. Edison will make some small lamps for sleeping rooms." In the office attached to Mr. Edison's laboratory were three lights, which had been constantly burning a day and night. The carbon paper slips did not show the least deterioration and to all appearances were good for almost an indefinite length of time. One of Edison's associates was busily engaged in the laboratory to-day perfecting an invention that he hopes will supersede the old system of telegraphy. It is somewhat similar to the old automatic and produces a fac simile of the original message at the other end of the line. On a short circuit at the Park it has worked with complete success, and the inventor claims that it will operate over a wire 1,000 miles in length.

MENLO PARK, N. J., Dec. 24.—The little charred paper horseshoes are yet illuminating Edison's laboratory at 10 o'clock this evening. Besides this, there are five houses in the place lighted in the same way and three Christmas trees. Not one of the lamps thus far has been destroyed. It is a jubilant Christmas eve, and Edison has been in wonderful spirits. For four days and nights at the end of last week and the beginning of this week he did not once have his boots off. He was working and watching night and day. Now he says his work is done, and he is going to have a rest. The lamps which were first lighted have now been burning 130 hours with only a few short intermissions. On Mr. Edison's basis of calculation, that four hours and a half is the time that families use artificial light, these 130 hours are equivalent to thirty days of service.

wain, but not before it had emitted a light of several gas jets. Eagerly the inventor hastened to examine under the microscope this curious filament, apparently so delicate, but in reality much more infusible than platinum, so long considered one of the most infusible of metals. The microscope showed the surface of the filament to be highly polished and its parts interwoven with each other.

THE PAPER LIGHT.

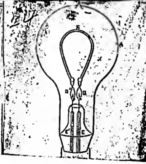
It was also noticed that the filament had obtained a remarkable degree of hardness compared with its fragile character before it was subjected to the action of the current. Night and day, with scarcely rest enough to eat a hearty meal, or catch a brief repose, the inventor kept up his experiments, and from carbonizing pieces of thread he went to splinters of wood, straw, paper and many other substances never before used for that purpose. The results of his experiments showed that the substance best adapted for carbonization, and the giving out of incandescent light, was paper preferably thick like cardboard, but giving good results even when ye[...] thin. The beautiful character of the illumina[...] and the steadiness, reliability and non-fusibility [of] the carbon filament were not the only elements [...] dant in the new discovery that brought joy to [the] heart of Edison. There was a further element [...] the less necessary because of its being hidden [...] element of a proper and uniform resistance to [the] passage of the electric current.

The inventor's efforts to obtain this element [...] been by far the most laborious of any in the hist[ory] of his work from the time he undertook the t[...] and without it absolute success to electric incan[des]cent illumination could not be predicated, [...] though all the other necessary properties were p[res]ent in the fullest degree.

Passing over the scores of experiments made [...] the discovery that the carbon framework of a [...] piece of paper or thread was the best substance [...] sible for incandescent lighting, we come to con[sider] the way in which the same is prepared at the [pres]ent time in the laboratory.

MAKING THE PAPER CARBON.

With a suitable punch there is cut from a pi[ece of] "Bristol" cardboard a strip of the same in the [shape] of a miniature horseshoe, about two inches in le[ngth] and one-eighth of an inch in width. A numb[er of] these strips are laid flatwise in a wrought [iron] mould about the size of the hand and separated [from] each other by tissue paper. The mould is then co[vered] and placed in an oven, where it is gradually [raised] to a temperature of about six hundred degrees [Fah]renheit. This allows the volatile portions [of the] paper to pass away. The mould is then place[d in a] furnace and heated almost to a white heat, an[d then] removed and allowed to cool gradually. On [open]ing the mould the charred remains of the little [horse]shoe cardboard are found. It must be tak[en out] with the greatest care, else it will fall to [pieces]. After being removed from the mould it is pla[ced in] a little globe and attached to the wires lead[ing to] the generating machine. The globe is th[en con]nected with an air pump, and the latter is [then] set to work extracting the air. After tha[t has] been extracted the globe is sealed, and the l[amp is] ready for use. Figure 7 shows the lamp comp[lete].



THE PERFECTED LAMP.—FIGURE 7.

THE GENERATING MACHINE.

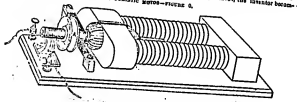
Mr. Edison's first experiments in machines for generating the electric current did not meet with success. His earliest apparatus was in the form of a large tuning fork, constructed in such a way that its ends vibrated with great rapidity before the poles of a large magnet. These vibrations could be produced with comparatively little power. Several weeks of practice proved, however, that the machine was of [...]

The entire system embraces an amount of work so extensive that one naturally wonders how a single man in such a brief space of time as fifteen months could possibly have planned and perfected it all. And surprise becomes greater when it is considered that during this period Edison found time to make other inventions. A sextuplex telegraph, or apparatus for sending six messages on one telegraph wire in opposite directions simultaneously, saw life during the progress of the electric light, patents for the same having only just been issued. Several new and important improvements to his chalk telephone, by which the efficiency of that invention is greatly increased, also attest his industry and versatility of genius.

POLYFORM.

But perhaps the latter quality is more strikingly exhibited in his polyform or preparation by which he is enabled to bid defiance to sick headaches, neuralgia and other nervous diseases, and to make himself largely independent of physicians in times of ailment. The polyform grew out of necessity. Being considerably afflicted with neuralgia and obtaining no relief from his physician, Edison set about becoming his own doctor. His chemical laboratory, one of the most complete in the United States, furnished him an ample field from which to draw. Experiment followed experiment, the inventor becoming more determined in proportion as his neuralgia grew more painful. At last he obtained a combination of chemicals, a slight application of which to the face immediately relieved his pain. Gratified at his success, but hardly yet convinced, he tried the preparation on others similarly afflicted and with equally satisfactory results.

THE DOMESTIC MOTOR—FIGURE 6.



"IN COLOQUE VILL."

About this time there happened to stroll into the laboratory one day a dilapidated tramp on his periodic begging expedition from place to place. Now, this tramp was a particularly unfortunate one, his poverty being hardly more distressing than his physical ailments. One of his legs was swelled with rheumatism, neuralgia coursed along his face and a dozen or more sores and bruises made him a veritable Job. Happening to meet him Edison saw in him a most excellent subject for further polyform experiments. A hearty meal and a little change readily procured the tramp's consent, and soon the inventor was subjecting his new acquaintance to all sorts of chemical experiments. For more than a week the tramp found food and lodging in Menlo Park, giving in return a few hours of his time every night to be experimented upon. By the time his engagement was over his rheumatism and neuralgia had disappeared, and his sores were well nigh healed. The news of the tramp's good fortune soon spread, and now it is no uncommon thing for neighbors to come to the inventor's laboratory from miles around to request a little polyform—a request which the inventor always good naturedly complies with.

GOLD "TAILINGS."

The very, very latest enterprise of the indefatigable scientist is a scheme for obtaining gold out of "tailings," or the sand thrown away by miners as having been worked out. Rumor has it that Edison has succeeded in obtaining a chemical preparation which will take from $200 to $300 per ton out of "tailings" from which the present processes can obtain nothing. The matter, however, is as yet a profound laboratory secret.

ELECTRIC LIGHTING BEFORE EDISON.

Among its other properties electricity has that of developing heat. A substance through which an electric current is made to flow becomes heated to a degree proportioned first to the strength of the current, and secondly to the size and character of the

The [...] now is that of a horse-shoe, but there [is no] reason why it might not be a circle, a [...] a triangle, or any other form [...] personal taste might prefer. The light could be readily built into any form or design of art and made to be a picture. The problem with Mr. Edison seems to [...]

The difficulty of subdividing the electric current is supposed to have been overcome by making a vacuum in every lamp. He has neither oxygen, nitrogen, hydrogen or carbon as part of his fuel. The light passes from point to point of carbon, but there is no oxygen to consume his carbon. He gets light without heat. The flame is purely electric, but it burns nothing, for carbon will not burn unless it comes in contact with oxygen.

Art and Scientific Entertainments.

No city of the size of Newark has so many amusements and social entertainments. The greater number are given for the benefit of churches, Sunday Schools and local charities. The most of them are of the lightest possible character; pleasant, innocent and easily managed, but not often instructive. They have interfered largely with costlier and professional amusements, and very seriously with lectures, con[...] [pro]gramme of entertainment that [is in]structive. EDISON'S ELECTRICITY

Washington Post

MENLO PARK ILLUMINATED WITH THE NEW LIGHT.

Dec 25 1879

Complete Success of the Carbon Paper Slip Illuminator—Scenes at the Home of the Great Inventor—The Death-Knell of Gas Companies.

Special Dispatch to THE POST.

MENLO PARK, N. J., Dec. 24.—This little village was illuminated with Prof. Thomas A. Edison's electric light this evening. Only four outdoor lamps were in operation, but electric burners to the number of twenty-eight were distributed in a dozen houses and the new light was pronounced a perfect success. It was demonstrated by illumination that the light of each of the so-called burners was fully equal to that produced by the ordinary gas-jet in the street-lamp or dwelling-house. Only two electric generators were in use to-day to supply the twenty-eight burners which were in operation, but with additional or more powerful generators the intensity of the light, Mr. Edison said, could be increased. A third generator will be finished in a day or two, and then a dozen or more additional burners will be set going. There was a marked difference between the light of the carbon paper burners at Menlo Park and the intense dazzling light given by the electric lamps which have for some time past been used in New York and other cities. The painful scintillation of the latter, caused by innumerable sparks chasing each other over the metal, instead of the carbonized retainer, is entirely avoided. After the visitors had witnessed the effect of the illumination from the lamps and from the outside of the houses, they were permitted to enter several of the private residences and judge of the utility of the new light for household purposes. One gentleman had an electric light in one of the sleeping rooms of his house. He said that the only fault he found with the light was that it was too bright. Said he, "I must either allow it to remain on full head or turn it off entirely. There is no intermediate point, but I presume Mr. Edison will make some small lamps for sleeping rooms." In the office attached to Mr. Edison's laboratory were three lights, which had been constantly burning a day and night. The carbon paper slips did not show the least deterioration and to all appearances were good for almost an indefinite length of time. One of Edison's associates was busily engaged in the laboratory to-day perfecting an invention that he hopes will supersede the old system of telegraphy. It is somewhat similar to the old automatic and produces a fac simile of the original message at the other end of the line. On a short circuit at the Park it has worked with complete success, and the inventor claims that it will operate over a wire 1,000 miles in length.

MENLO PARK, N. J., Dec. 24.—The little charred paper horseshoes are yet illuminating Edison's laboratory at 10 o'clock this evening. Besides this, there are five houses in the place lighted in the same way and three Christmas trees. Not one of the lamps thus far has been destroyed. It is a jubilant Christmas eve, and Edison has been in wonderful spirits. For four days and nights at the end of last week and the beginning of this week he did not once have his boots off. He was working and watching night and day. Now he says his work is done, and he is going to have a rest. The lamps which were first lighted have now been burning 136 hours with only a few short intermissions. On Mr. Edison's basis of calculation, that four hours and a half is the time that families use artificial light, these 136 hours are equivalent to thirty days of service.

THE EVENING STAR: TUESDAY, JAN[illegible]

EDISON HAS ACCOMPLISHED, [illegible] to Accomplish, in His Electric Light.

We have taken considerable pains to look into the present and probable results of Mr. Edison's labors in this direction, and will give them here as concisely and clearly as possible. Let us first see what is claimed by Mr. Edison as to the present perfection of the electric light and what he says regarding its future. Mr. Edison claims that the electric light has been so much improved in his hands that it is almost, if not quite, in a state to compete with gas, and promises in a short time to improve it so much more that, all things taken into account, it will be far superior to gas. He also thinks that he can advantageously employ electricity to drive machinery.

The palpable fallacy of this last proposition is perfectly apparent when we consider that the source of this electricity is mechanical force, and to use this electricity to again produce mechanical force would be subjecting our original power to a transformation the only effect of which would be an immense loss of power.

Before discussing the comparative merits of gas and electricity as a means of lighting a city throughout, we should explain what the electric light is, how produced, and how maintained. When the end wires of a powerful battery are touched together and then slightly separated, an intense bright light is produced in the intervening space, which on account of its curved form has been called the voltaic arc. If the current from the battery is not immediately stopped, the points of the wires soon become heated and melt, and consequently if the ends are not moved nearer to each other, the interval between them increases, and finally becomes so great that the electricity can no longer leap from one wire to the other, and the light suddenly ceases. But if the wires are again brought together and separated as before, the light is reproduced.

If, however, instead of touching the wires, two strips of hard conducting carbon are used on the ends, the light becomes of dazzling brilliancy, and is too strong for the eye to look upon directly. It may, nevertheless, be viewed through a piece of smoked glass, or thrown upon a screen and then examined. This is the first form of the electric light, and as a powerful light it is to-day in advance of any other.

In temperature, as well as brilliancy, the voltaic arc far surpasses all other artificial sources of heat. By means of it Despretz has succeeded in reducing even the diamond to vapor. In this arc the light evolved is due in considerable measure to the oxidation of the carbon by the atmosphere, but it is also due to the heat generated by the electric current encountering resistance as it passes through the space between the carbon points. As the light continues, particles of carbon are carried across the arc in both directions, but mostly in the direction of the positive current. The curious fact that the positive carbon wastes away much more rapidly than the negative, is also very noticeable. This may be said to be the first class of electric lights, of which there are four.

A second class of lights are those in which the carbon points are placed in a sealed transparent globe, free from oxygen, or in vacuo. In this case, of course, there is no oxidation, but one pole is being constantly increased at the expense of the other, as in the first class of lights.

[illegible] made to pass [illegible] high resistance, not in [illegible] as a non-conductor [illegible] there is no interval [illegible] ous. In this case a sufficient [illegible] render the particles of carbon [illegible] of the light is also due to the [illegible] the carbon on the surface [illegible] iridium, platinum, etc., have been used, and have given much better results.

A fourth class of [illegible] which our attention has been called by Mr. Edison—but not invented by him—is the same as the third, except that the light is produced in a sealed transparent envelope free from oxygen, or in vacuo. This last method is superior to the other three, because it furnishes a lamp which is cheaper to make, will give a light not too powerful, and will last indefinitely, since there can be no combustion.

The electric lamp invented and now used by Mr. Edison to light Menlo Park, and that which is conceded to approach nearest to the solution of the problem of electric lighting, consists of a small horseshoe of about three inches in circumference and one-sixteenth of an inch in width, cut from a piece of thick white paper. After being compressed it is placed in a small muffle furnace and carbonized or charred. The horseshoe is then fixed in the center of a glass globe, of about three inches diameter with two small platinum wires connected to its extremities. The air in this globe is finally exhausted to the utmost extent of one-millionth of its original volume, and the globe is sealed with the platinum wires brought out at the place of sealing.

This is the whole of Mr. Edison's invention in regard to electric lighting as now carried on, viz.: the rendering of a piece of charred paper, in vacuo, incandescent, by the passage of an electric current.

Quite as important a part of the electric light as the lamp is the manner in which sufficient electricity to produce many such lights may be procured. It has been found vastly cheaper and much easier to generate electricity in large quantities by means of mechanical force, than by chemical means, as in a galvanic battery.

The operation by which the transformation of mechanical force is effected depends upon the fact that when a bar of soft iron, surrounded with a coil of insulated wire, is rapidly magnetized and demagnetized a current of electricity is generated in the wire at each change of magnetic state. The strength of these currents is proportional to the amount of magnetism given to the bar, and to the rapidity of change in its magnetic strength. In the machine these bars of soft iron are caused to revolve rapidly past the poles of a magnet, thereby becoming magnetized and demagnetized, and producing currents in the coils, which succeed each other with such rapidity that they practically form one continuous current. Since the strength of the current is dependent upon the velocity at which the machine is made to operate, a very fast revolution is necessary to secure a comparatively strong current.

Within the last ten or fifteen years these machines have been improved to a very great extent; but as we cannot discover what is the electrical equivalent of mechanical force, or how much electricity a certain amount of mechanical force is capable of generating, we have no means of judging how far we are from possessing a perfect machine, or, in other words, of how much more improvement this method of producing electricity is susceptible.

It may be asked, Why may not a new mode of generating electricity be discovered? Such a question is ridiculous. We might as well ask, Why may not an entirely new kind of light be discovered? At present we know of but two ways of producing electricity of this nature; viz.: by magnetism, as just described, and by chemical action. But we do not understand how mechanical force is transformed into electricity by magnetism, or how electricity is generated in a battery—whether by heat, chemical action or what.

These—the lamp and the generating machine—constitute the electric light. We do not know to what extent either may be improved. It is therefore asked by some persons, Why may it not be made to supersede gas by further discoveries? We will now give the principal reasons why electricity cannot compete with gas at present for domestic purposes.

Primarily, their relative costs should be considered. The question may be asked: How is it possible to produce as much light with a given amount of heat by transforming the heat into electricity and then back to heat, as by utilizing the heat directly? This is possible simply because we obtain only about 8 per cent. of the amount of light which the energy expended in making gas is able to produce. That is to say, that if all the energy locked up in a pound of coal could be liberated and converted wholly into light, it would give twelve and a half times the amount of light now obtained from the gas made from a pound of coal.

To illustrate: Perhaps, on the average, one pound of illuminating gas will give seventy-five candle-lights per hour. The energy obtained from one pound of illuminating gas by complete combustion is equal to 16,000,000 foot pounds of work. This, if burned in an hour, would average about 250,000 units of work in a minute or about 3,500 foot pounds per minute for every candle-light. That is to say, the amount of illuminating gas which will give one candle-light in an hour will yield 3,500 foot pounds in a minute. A very large electric light—perhaps 10,000 candles—does not consume more than thirty foot pounds of energy per minute for every candle-light, and even a small one not more than 200. So it might not seem extravagant to assume that one pound of gas per hour could be burned in a good furnace, under a good boiler, and produce steam enough to drive a steam engine, and the engine a magneto-electric machine, which should supply five electric lamps that would give more light than five gas lamps, each consuming one-fifth of a pound of illuminating gas per hour. But it must be remembered that this is the result of using an electric light of two carbon points, which could not be used to light private houses, because it is too powerful, is difficult to manage, and cannot be subdivided.

To this kind of light there are also the objections that it is expensive, liable to get out of order and the carbons require renewal. Electric lamps, consisting of a thin strip of platinum, have been devised by Mr. Edison to meet these objections, and he succeeded in obtaining a very good light from them. But the lamp, which is now thought to be far in advance of all others, is the paper horseshoe in vacuo. This lamp is the best adapted to domestic use, for three reasons: First, because it gives a light of the required brilliancy, and is steady; second, it is not liable to get out of order, and third, it will last indefinitely, requiring no attention. But the main feature of this lamp seems to have been overlooked, viz.; that it is much more expensive.

[illegible] cost is that small lights are relatively much more expensive than large ones. For example: If the current from a single light be divided so as to produce two lights, the latter will not each shine with half the intensity of the single light. This is because the light produced increases much faster than the strength of the current. The reason of which is, that before the carbon, platinum or paper becomes luminous, a certain amount of electricity is required to heat it; and this electricity is consequently of no value so far as giving light is concerned. There is also another reason: the resistance increases as the temperature of the substance, the greater the resistance the stronger being the light.

Another very serious objection to the introduction of the electric light is the liability of the wires to get out of order or to be broken. No idea of the danger of wires to get out of order or be broken can be formed by any one who has not had considerable experience in the laying and use of wires. That they are more likely to break than gas-pipes will not be doubted, and when they have broken there can be no more light beyond the fracture. But not so with gas: for when a gas-pipe breaks, the flow is not stopped or lost to any extent as a general rule, and the lights beyond are not seriously affected. Again, if the wire should break in the house and should leave a sufficient interval for a small electric arc to be formed, what is to prevent it from setting fire to the insulation, and perhaps the house, unless laid in iron pipes or in some such way?

Another serious objection is the liability of the generating machine to break or get out of order. Still another is the fact that no electricity can be stored up and kept in reserve for any time.
